The classic findings in viral encephalitis include perivascular mononuclear cell inflammation, neuronal destruction, neuronophagia, and microglial nodules,[226] with most of the abnormalities seen in the gray matter of the brain. Tissue sections of the brain generally reveal meningeal congestion and mononuclear infiltration, perivascular cuffs of lymphocytes and plasma cells, some perivascular tissue necrosis with myelin breakdown, neuronal disruption in various stages (including ultimately neuronophagia), and endothelial proliferation or necrosis. The severity and the extent of observed lesions vary with the infectious agent and with the degree of reaction of the host. The cerebral cortex, especially the temporal lobe, often is affected severely by herpes simplex virus, and arboviruses tend to affect the entire brain.[220] Intranuclear inclusions are suggestive of a member of the Herpesviridae. Rabies has a predilection for the basal structures; involvement of the spinal cord, nerve roots, and peripheral nerves varies. Negri bodies, if identified, are pathognomonic for rabies. Although rabies has one of the highest fatality rates of any infectious disease, brain tissue shows relatively benign neuropathologic changes without evidence of neuronal death. In contrast, *Naegleria* causes marked hemorrhagic necrosis, especially in the olfactory bulbs and cerebral cortex.[253] The pathologic process seen in patients with herpes simplex encephalitis is also characterized by a hemorrhagic necrosis but in different locations (i.e., the temporal and frontal lobes).[271]

In contrast to acute viral encephalitis where gray matter is predominantly affected, the white matter is most affected in postinfectious encephalitis. A marked degree of demyelination with preservation of neurons and their axons is considered to be predominantly postinfectious or parainfectious (autoimmune) encephalitis.

Finally, some infectious agents such as *Mycobacterium tuberculosis* and fungi can cause encephalitis-like symptoms without parenchymal involvement. For example, tuberculosis can lead to hydrocephalus and cranial nerve palsies. Other agents, such as varicella-zoster virus and coccidioidomycosis, can cause vasculitis resulting in infarctions in the brain with resultant focal neurologic deficits mimicking encephalitis.[454]

CLINICAL MANIFESTATIONS

The clinical findings in encephalitis are determined by the severity of involvement and anatomic localization of the affected portions of the nervous system, the inherent pathogenicity of the offending agent, and the immune and other reactive mechanisms of the patient ("host factors"). Evidence of brain parenchymal involvement is the hallmark of encephalitis. Children with encephalitis may show evidence of diffuse disease, such as behavioral or personality changes; decreased consciousness; and generalized seizures or localized changes, such as focal

seizures, hemiparesis, movement disorders, cranial nerve defects, and ataxia. Some children may seem to be mildly affected initially only to lapse into coma and sudden death. In others, the illness is ushered in by high fever, violent convulsions interspersed with bizarre movements, and hallucinations alternating with brief periods of clarity and the children emerge with relatively few sequelae.

Specific forms of encephalitis or complicating manifestations of encephalitis include Guillain-Barré syndrome and related syndromes, acute transverse myelitis, acute hemiplegia, brain stem encephalitis, and acute cerebellar ataxia. Acute cerebellar ataxia is characterized by an abrupt onset of truncal ataxia resulting in varying degrees of gait disturbance and balance abnormalities. Children with this illness have tremulousness of the head and trunk when in the upright position and of the extremities when attempting to move them against gravity. The duration of illness varies from 3 to 4 days to several weeks. Acute cerebellar ataxia often follows chickenpox or other viral illnesses. In one study, 3 percent were related to immunization.[103] Approximately 90 percent of patients recovered completely from the ataxia, but 20 percent had transient behavioral or intellectual disturbances. Five percent had persistent learning problems.

Most commonly, the initial manifestations resemble an undifferentiated acute systemic illness with fever, headache, or, in infants, screaming spells, abdominal distress, nausea, and vomiting. Signs of an associated mild nasopharyngitis may suggest a respiratory tract infection. As the temperature increases, new findings direct attention to the nervous system: mental dullness eventuating in stupor; bizarre movements; convulsions; nuchal rigidity, often not as pronounced as in purely meningitic illness; and focal neurologic signs, which may be stationary, progress, or fluctuate. Loss of bowel and bladder control and unprovoked emotional outbursts may occur.

A wide range of severity of clinical manifestations exists even with the same etiologic agent. Nevertheless, some organisms show tropism for a specific area of the brain and consequently specific clinical characteristics are appreciated. Arboviruses often can cause diffuse brain involvement with global impairment, whereas herpes simplex virus type 1 almost universally involves the temporal lobe. The classic features of herpes simplex encephalitis include fever, altered level of consciousness, dysphagia, focal motor seizures, and hemiparesis; almost all adults with this disease exhibit these features. Children, however, may have atypical features and can have extratemporal lobe involvement.[134] One study identified up to one fourth of children with atypical features, such as ataxia, decreased visual acuity, or tonic-clonic seizures.[134] Primary varicella infection is often associated with cerebellar inflammation, and patients present with ataxia and nystagmus and may or may not have cognitive impairment. Individuals with Epstein-Barr virus encephalitis can sometimes have micropsia, macropsia, and/or size distortion, called "Alice in Wonderland" syndrome. The occurrence of seizures is variable depending on the pathogen. In *Bartonella* encephalopathy, generalized seizures are common,[54] whereas they are unusual in West Nile virus infection.[382] Individuals with rabies often have rapidly progressive encephalitis. Paresthesia at or near the bite site is unique to rabies. Most (~80%) patients with rabies have the "furious" form, characterized by agitation, hydrophobia, delirium, and seizures. Patients with the "paralytic" form (~20%) have ascending paralysis, followed by confusion and coma. Although these two forms are described, it is not unusual for patients to have features of both.

Brain stem encephalitis is a rare disorder, but it is important because clinical signs appear similar to those of a brain stem glioma. The differentiation is important because treatment is radically different. The differentiation is made by the time of onset of symptoms and by the course. Brain stem glioma usually has slowly progressive symptoms developing over the course of several weeks or months. Brain stem encephalitis evolves over 1 to 7 days. Both disorders may be associated with radiographic evidence of brain stem enlargement. Brain stem encephalitis resolves after 1 to 4 weeks, whereas a tumor continues to progress until radiation therapy is given.

Most cases of brain stem encephalitis seem to be postinfectious and are similar to postinfectious cerebellar ataxia, Miller-Fisher syndrome, or Guillain-Barré syndrome. The conditions often overlap.[14] In postinfectious cases, the onset of brain stem encephalitis begins 1 to 3 weeks after a nonspecific viral infection. Brain stem encephalitis has been reported to occur, however, as a result of specific, identifiable, and some treatable infectious agents, including herpes simplex virus,[16,282,337,362,377] varicella-zoster virus,[368,414] cytomegalovirus,[154,232] enterovirus 71,[209,211] West Nile virus,[116] *M. pneumoniae*,[262,405] *L. monocytogenes*,[6,11,12,17,26] *Propionibacterium acnes*,[53] and *Campylobacter jejuni*.[466]

Some patients with a typical clinical picture of brain stem encephalitis have had anti-GQ1b antibodies in the serum,[86] which may represent a subgroup of postinfectious brain stem encephalitis cases. Brain stem encephalitis may arise in HIV-infected patients and may be due to a treatable cause, such as herpes simplex encephalitis.[154,191,367] In an enterovirus outbreak in Taiwan, the most common neurologic complication was rhombencephalitis, and a 14 percent mortality rate was reported.[209,211]

DIFFERENTIAL DIAGNOSIS

The evaluation of a patient with an acute CNS illness (encephalopathy) must be considered carefully, and the sequence of tests should be dictated by the specific circumstances of the individual patient. Several disease processes may have presentations similar to infectious causes.

The differential diagnosis of acute encephalopathy includes the following:

- Autoimmune (anti–*N*-methyl-D-aspartate receptor [NMDAR] encephalitis has recently been found to be one of the leading causes of noninfectious encephalitis in children)
- Acute demyelinating disorders, including ADEM, acute multiple sclerosis, and acute hemorrhagic leukoencephalitis

- Other postinfectious diseases, including Guillain-Barré syndrome (including Miller-Fisher variant), brain stem encephalitis, and acute cerebellar ataxia
- Status epilepticus, especially nonconvulsive status epilepticus, such as complex-partial status or absence status
- Metabolic diseases, such as hypoglycemia, uremic encephalopathy, hepatic encephalopathy, and rare genetic inborn errors of metabolism, including disorders of glucose or ammonia metabolism
- Toxic disorders, such as drug ingestion or Reye syndrome
- Mass lesions, such as tumor or abscess
- Subarachnoid hemorrhage from arteriovenous malformation or aneurysm
- Embolic lesions caused by bacterial endocarditis
- Acute confusional migraine

EVALUATION OF A PATIENT WITH ENCEPHALOPATHY OR POSSIBLE ENCEPHALITIS

Although many cases of encephalitis remain without a cause, and many of the causes are not treatable per se, a thorough diagnostic evaluation is important. For example, the identification of a specific cause may be helpful for prognosis, lead to the discontinuation of unnecessary antimicrobial therapy, and be useful for potential prophylaxis of contacts and initiation of public health interventions. Obtaining a careful history and performing a physical and neurologic examination are essential in all patients who have a history consistent with encephalitis. The differential diagnosis previously presented indicates that encephalitis is only one of many disorders that can manifest as an acute or subacute picture of encephalopathy. Although the diagnosis of encephalitis may be determined best with a lumbar puncture and evaluation of the CSF, lumbar puncture may be contraindicated in some disorders and, if performed inappropriately, may lead to serious complications and even death. A child who has a cerebellar tumor with acute obstruction of the fourth ventricle may have a decreasing level of consciousness caused by the rapidly increasing intracranial pressure. Nuchal rigidity may be present. The family may not have recognized the more subtle changes in cerebellar functions for the months before the acute obstruction developed and may give a history of acute encephalopathy. In that case, a lumbar puncture could result in herniation through the foramen magnum. It is essential that the patient be assessed for the possibility of increased intracranial pressure and the potential for herniation.

The patient's history should be reviewed carefully, questioning specifically for symptoms of neurologic problems that manifested in the days or weeks before the acute disorder occurred. The physical examination must be performed with special attention given to focal neurologic abnormalities, cerebellar signs, and evidence of increased intracranial pressure. Conducting a careful funduscopic examination is important but may be impossible in an agitated patient or young child. The presence of papilledema indicates that neuroimaging should be performed before doing the lumbar puncture. If spontaneous venous pulsations are noted on funduscopic examination, intracranial pressure is not increased and the lumbar puncture can be done without imaging.

In addition to a lumbar puncture, neuroimaging and obtaining an EEG can help in determining the cause of the encephalopathy and the most appropriate course of therapy. Results of the history and physical examination provide a guide to the most appropriate first test to perform, but generally neuroimaging is the most likely to be helpful. The exception would be a child in nonconvulsive status epilepticus. The history may suggest encephalitis as the most likely diagnosis, but, in some patients, nonconvulsive status epilepticus may be clinically indistinguishable from encephalitis.

Neuroimaging

Most patients with encephalopathy should undergo neuroimaging to aid diagnosis of treatable conditions, such as herpes simplex encephalitis. Computed tomography (CT) is helpful in the acute setting to identify abnormalities, such as tumor or abscess, and to decide whether performing a lumbar puncture is safe. However, CT is not as helpful as magnetic resonance imaging (MRI) in detecting the subtle changes associated with encephalitis.[51,273,387] In many cases of viral encephalitis, CT and MRI yield normal results or only nonspecific changes, such as swelling[448] or edema.[273] An important exception is herpes simplex encephalitis.

As previously noted, MRI is more sensitive than is CT. In one study, CT initially was positive in only 42 percent of cases whereas MRI was positive in all cases.[245] MRI in HSV encephalitis characteristically shows abnormalities in the medial temporal lobes, inferior frontal cortex, and insula.[272,450] The likelihood of finding the abnormalities may be increased by using T2-weighted imaging and fluid-attenuated inversion recovery (FLAIR) sequences[20,235] or diffusion-weighted imaging.[384,422] Diffusion-weighted MRI seems to be more sensitive than is FLAIR or T2-weighted sequences in the detection of herpes simplex virus or other encephalitides.[430] The localization of abnormalities may differ, however, from the classic pattern in young children. In neonatal herpes encephalitis, widespread changes occur in the periventricular white matter, often sparing the medial temporal and inferior frontal lobes. Another pattern has been described in children aged 4 to 13 months in whom the cortex and adjacent white matter of the hemispheres were abnormal.[272]

In addition to herpes, other encephalitides may yield abnormal neuroimaging. CT and MRI results often are abnormal in disorders caused by arbovirus or enterovirus infections. When imaging is abnormal, it usually is nonspecific, showing areas of decreased density (with CT) or increased signal intensity (with MRI) in the gray or white matter. A variety of MRI abnormalities with certain viral encephalitides have been reported. The basal ganglia, brain stem, and thalami have been reported to be

abnormal on MR images of patients with eastern equine encephalitis,[122] Japanese encephalitis,[210,257] and enterovirus 71.[209,211] These differences help to distinguish herpes simplex virus from other, nontreatable causes of viral encephalitis.

Postinfectious disorders most often are associated with selective oligodendrocyte involvement.[28] Imaging shows increased signal in white matter with T2-weighted MRI or low-density white matter with CT.[25,45,197,240,327] Patients with acute hemorrhagic leukoencephalitis, a rare disease that is rapidly progressive and often fatal, may have a clinical picture similar to that of herpes simplex encephalitis. In contrast to herpes simplex virus infection, the CT results often are abnormal within the first 1 or 2 days.[369,446] If a patient with suspected herpes simplex encephalitis has abnormal CT results early in the course, acute hemorrhagic leukoencephalitis should be considered.

Another imaging technique that has been reported to be helpful in establishing the diagnosis of encephalitis is single-photon emission computed tomography (SPECT). Initial reports suggest that SPECT is more sensitive than is CT. Ackerman and colleagues[2] found that SPECT showed greater sensitivity and more precise localization than did conventional radionuclide scanning and CT. Launes and associates[268] studied 14 patients with encephalitis and found that SPECT detected temporal lobe abnormalities in all 6 of the patients with herpes simplex encephalitis and yielded normal results in the remaining 8 whose disease had other causes. A few cases of normal MR images but abnormal SPECT scans in patients with herpes simplex encephalitis have been reported[196,292]; this is less likely to occur with newer MRI sequences such as diffusion-weighted imaging. If SPECT is performed, technetium-99m hexamethylpropyleneamine oxime seems to be superior to technetium-99m ethyl cysteinate dimer.[115,139] Generally, SPECT should be reserved for cases in which the MRI results are normal and the EEG is nondiagnostic but in which herpes simplex encephalitis is still strongly suspected. Intracranial ultrasonography in neonates has been shown to be helpful in establishing the diagnosis and in follow-up of infants with herpes simplex virus or cytomegalovirus infections.[293]

Electroencephalography

Generally, an EEG should be obtained in most patients with encephalitis. The EEG results of patients with encephalitis are often nonspecifically abnormal, showing diffuse slowing. Crucial exceptions to the general rule exist, however.

In acute encephalopathy, comatose patients may be in nonconvulsive status epilepticus,[424] which requires immediate and appropriate intervention. The presence of periodic lateralized epileptiform discharges (PLEDs) on an EEG strongly suggests the possibility of herpes simplex encephalitis but also may be an indication of seizures.[27] Early in the course of herpes encephalitis, generalized slowing of the background frequencies and focal slowing over the affected temporal lobe may occur. Within a few days, the characteristic PLEDs pattern develops in most cases. Later in the course, the background activity between the bursts of PLEDs gradually may flatten. Occasionally, other areas of the brain seem to be involved, primarily with herpes simplex virus. PLEDs, although strongly suggestive of herpes simplex encephalitis, are not diagnostic. PLEDs have been reported with stroke and infectious mononucleosis encephalitis,[173] and periodic complexes are characteristic of the slow virus and prion disorders, including Jakob-Creutzfeldt disease and subacute sclerosing panencephalitis.

The EEG abnormalities in neonatal herpes encephalitis are similar to those in older patients. The characteristic EEG results yield periodic or pseudoperiodic complexes, usually triangular or sharp waves, occurring in a multifocal pattern.[307] In one study of 34 infants with herpes simplex encephalitis, EEGs were obtained in 21, the results in 19 being abnormal. The results of 3 showed only focal slowing, but the other 16 showed the characteristic periodic or pseudoperiodic complexes.[372] The authors reviewed 500 other neonatal EEG records and found 20 with similar complexes; 11 patients had meningoencephalitis of unknown etiology, 3 had hemorrhage, and 2 had asphyxia. Four were placed in a miscellaneous category. Periodic or pseudoperiodic complexes on a neonatal EEG strongly suggest herpes simplex encephalitis, but they are not diagnostic.

DIAGNOSIS

A meticulous history is essential and must evaluate exposure in the previous 2 to 3 weeks to illness in contacts; exposure to mosquitoes, ticks, and animals during recent vacations or picnics or other outdoor activities; awareness of illness in animals in the patient's environment; recent travel from the home area; recent injections of any kind; and the possibility of accidental exposure to heavy metals, pesticides, or other questionable substances. The CSF must be examined carefully to exclude other disorders that respond to specific therapy. Smears for bacteria, appropriate rapid antigen-identification tests, and cultures of the CSF are mandatory; the history and clinical findings may indicate the need for acid-fast stain and culture of the sediment for mycobacteria. Although often not done because of inconvenience, opening CSF pressures should be measured. Molecular testing has advanced the diagnostics for encephalitis overall, but there are a number of important limitations of molecular diagnostics (both false-positive and false-negative findings). In particular, it is important to understand that a positive polymerase chain reaction (PCR) test in the CSF does not necessarily equate with disease as well as a negative PCR test does not rule it out. Additionally, there is still a very important role for culture and serologic assays for the diagnosis of encephalitis. Recommended test types and "pitfalls" in testing are outlined in Table 36-1. A diagnostic algorithm is presented in Table 36-2.

The availability of PCR has revolutionalized the diagnosis of herpes simplex encephalitis. It has allowed the definitive and rapid diagnosis of HSV encephalitis to be established, eliminating the need for brain biopsy.[123,259,376,434,452] If, however, initial testing is negative for herpes simplex virus and herpes simplex encephalitis is strongly suspected (e.g., from results of temporal lobe

Table 36-2 **Diagnostic Algorithm**

All Cases

CSF

White blood cells, protein, glucose

Bacterial culture

Herpes simplex virus-1 PCR

Enterovirus PCR

Blood/Serum

Routine blood culture

Epstein-Barr virus (EBV) antibodies (if positive for acute infection, check CSF EBV PCR)

Hold acute serum and collect convalescent serum 10-14 days later for paired antibody testing.

Respiratory, Stool

Enterovirus PCR (respiratory, stool)

Enterovirus (stool)

Conditional

Host Factors

Neonate: herpes simplex virus-2 PCR (CSF), swabs of skin vesicles, mouth, nasopharynx, conjunctivae, and rectum (viral culture)

≤3 yr: parechovirus PCR (CSF and respiratory)

Immunocompromised: cytomegalovirus, human herpesvirus–6/7, JC virus, human immunodeficiency virus PCR (CSF)

Season and Exposure

Summer/fall: West Nile virus (WNV) IgM (CSF, serum), WNV IgG (paired serum) and other appropriate arboviruses as geographically relevant

Cat (particularly if with seizures and paucicellular CSF): *Bartonella* antibody (serum)

Animal bite exposure: rabies test*

Rodent exposure: LCM antibody (serum)

Tick and/or camping exposure: *Rickettsia* spp., antibody (serum), *Anaplasma* phagocytophila antibody (serum)

Swimming or diving in brackish water: *Naegleria fowleri* (wet mount)*

If history of sexual activity: herpes simplex virus-2 (CSF PCR)

Signs and Symptoms

Psychotic component or movement disorder: anti-NMDAR antibody (CSF and serum), and abdominal ultrasound evaluation for teratoma

Vesicular rash: varicella-zoster virus PCR (CSF)

Rapid decompensation (especially with bite history or foreign travel): rabies test*

Respiratory (during influenza season): influenza PCR (respiratory)

Diarrhea and seizure (especially young child): rotavirus (check stool for antigen), if positive then rotavirus PCR (CSF)

Laboratory Features

CSF protein >100 mg/dL or CSF glucose less than two thirds peripheral glucose and/or lymphocytic pleocytosis:

Mycobacterial tuberculosis: culture (CSF, respiratory), place PPD, and check IGRA, chest radiograph, fungal culture (CSF).

Fungal (specific types depend on geographic residence and/or travel to endemic areas): culture CSF *and* check antibody and antigen.

Balamuthia mandrillaris: contact health department/CDC for assistance with testing.

CSF eosinophilia: *Baylisascaris procyonis* antibody

Travel

Consider consultation with public health department concerning specific diseases such as arboviruses, rabies, and other diseases.

*Contact health department for assistance with testing.

CDC, Centers for Disease Control and Prevention; *CSF,* cerebrospinal fluid; *IGRA,* interferon gamma release assay; *LCM,* lymphocytic choriomeningitis; *NMDAR, N*-methyl-D-aspartate receptor; *PCR,* polymerase chain reaction; *PPD,* purified protein derivative.

neuroimaging), a second CSF specimen should be obtained and retested for herpes simplex virus by PCR because false-negative results can occur.[134,447] The etiology of encephalitis caused by other herpesviruses also has been determined by PCR assay of CSF.[110,294,431] Physicians should be aware, however, of some of the limitations in interpretation of PCR results in patients with encephalitis. For example, because Epstein-Barr virus infections result in latency in the lymphoreticular system (including B cells), when PCR on CSF is examined for this virus, low levels can be detected when it is not necessarily the cause of encephalitis. Serology as well as Epstein-Barr virus PCR should be performed. Similarly, testing the CSF by PCR for human herpesvirus–6 should be performed in some cases but can lead to false-positive results owing to latency. Additionally, for human herpesvirus–6 infections, the phenomenon of chromosomal integration of the virus can further confound the diagnosis.[444]

In addition to its use in herpesvirus infections, PCR can be useful for detected enteroviruses and parechoviruses, and in the future it is likely to be useful to identify other encephalitides.[38,247,274,334,359] For possible enteroviral encephalitis, because the CSF PCR is not always positive, it is therefore important to look for enteroviruses in multiple sites outside the CNS to maximize detection.[339]

In viral encephalitis, the CSF frequently is clear; the leukocyte count ranges from none to several thousand, often with a significant percentage of polymorphonuclear cells initially, moderate or no elevation of protein, and an initially normal level of glucose relative to the simultaneously determined blood glucose level. A nonviral entity should be considered in cases in which the CSF white blood cell count is high (particularly for values >1000 cells/mm^3), protein is greater than 100 mg/dL, and/or CSF glucose is less than two thirds of the serum value. For example, a lymphocytic pleocytosis with high protein

and low glucose values is often found in patients with fungal or *M. tuberculosis* meningitis-encephalitis. If eosinophils are identified in the CSF, a helminthic-parasitic infection should be considered such as *B. procyonis*, *A. cantonensis*, or *G. spinigerum*. Eosinophils in the CSF can also be seen in patients with coccidioidomycosis and *M. tuberculosis* infection.[351]

In any patient suspected to have viral meningoencephalitis, CSF, blood, feces, and throat swabs should be collected and sent to a laboratory offering viral diagnostic services. An additional serum specimen should be collected 10 to 21 days later. Although these studies may not provide an immediate diagnosis, they may give early warning of a specific epidemic and the use of specific antiviral chemotherapy may be indicated by the preliminary culture results.

Inquiry regarding recent illness, recent injections, and, especially, recent exposures away from the home environment sometimes is helpful. The incubation periods of some arboviruses are such that mosquito bites acquired at least 1 week earlier or insect bites now healed may give a clue. Occasionally, patients who have traveled to Africa or Asia in preceding weeks have encephalitis caused by viruses, trypanosomiasis, or falciparum malaria with bizarre systemic and CNS signs and symptoms.

Rabies should be considered in any patient with a rapid progression of illness. Hydrophobia, autonomic instability, extreme agitation, and seizures are often present. Paresthesia at the site of inoculation, if present, is an important diagnostic clue unique to rabies.

Anti-NMDAR, although not an infectious agent, deserves special mention given its relatively high frequency in the young population.[155] In a recent study, anti-NMDAR encephalitis occurred more than four times as frequently as herpes simplex virus type 1, West Nile virus, and varicella-zoster encephalitides and was the leading entity identified in California Encephalitis Project patients younger than 30 years of age. Seizures, language dysfunction, psychosis, and EEG abnormalities were significantly more frequent in patients with anti-NMDAR. Testing for this entity could lessen the need for additional testing and allow for a clear diagnosis.[155]

TREATMENT

Acyclovir should be used to treat herpes simplex and varicella-zoster virus encephalitis and perhaps encephalitis caused by Epstein-Barr virus. Cytomegalovirus encephalitis should be treated with ganciclovir, and oseltamivir should be considered for treatment of encephalitis caused by influenza viruses A or B. Specific antimicrobial treatment should be used for infections caused by spirochetes, *Chlamydia*, *Mycoplasma*, fungi, and parasites.

General treatment is nonspecific and empirical, aimed at maintaining life and supporting each involved organ system. The effectiveness of various recommended regimens in most instances has not been evaluated objectively. Until a bacterial etiology and, in particular, a brain abscess are excluded, parenteral antibiotic therapy should be administered.

Anticipating and being prepared for convulsions, cerebral edema, hyperpyrexia, inadequate respiratory exchange, disturbed fluid and electrolyte balance, aspiration and asphyxia, abrupt cardiac and respiratory arrest of central origin, cardiac decompensation, and gastrointestinal bleeding is crucial. The syndrome of disseminated intravascular coagulation may be an additional complication.

For these reasons, all patients with severe encephalitis should receive care in intensive care units. Cardiac monitoring should be maintained. Repeat CT and MRI are helpful in following the status of comatose patients and often show signs of brain swelling before the patient has the typical clinical indicators of intracranial pressure, such as Cushing triad (systolic hypertension, bradycardia, and slowing of respirations), dilated pupils, and decorticate or decerebrate posturing. The Cushing triad is an unreliable indicator of increased intracranial pressure, and, when the other signs of increased intracranial pressure occur, they often do so late in the course, when the patient's cerebral perfusion already is at risk.[296] As mentioned previously, the opening pressure should be determined when CSF is obtained. If a patient has a high opening pressure, close monitoring is advised with consideration of measures to decrease intracranial pressure. If brain swelling becomes a problem, placement of an intracranial pressure monitor may be necessary. The intracranial pressure should be maintained at less than 15 mm Hg if possible using the standard techniques for reduction of intracranial pressure, including hyperventilation, osmotic diuretics, and removal of CSF. As a last resort, inducing a barbiturate coma may be necessary. A related consequence of intracranial pressure is the syndrome of inappropriate antidiuretic hormone secretion. Careful monitoring of the fluid and electrolyte balance is essential in all seriously ill patients with encephalitis.

All fluids, electrolytes, and medications initially are given parenterally. In patients with prolonged coma, parenteral hyperalimentation is indicated. Normal blood levels of glucose, magnesium, and calcium must be maintained to minimize the threat of convulsions.

Status epilepticus caused by encephalitis should be treated vigorously using a structured protocol to ensure optimal control.[390,427] The current standard initial therapy is intravenous lorazepam 0.1 to 0.2 mg/kg, up to 4 mg maximum. Seizures associated with encephalitis may be refractory to the usual therapy, and other anticonvulsants may be required to achieve and maintain control of seizures. In patients who fail initial therapy and are in medically refractory status epilepticus, continuous EEG monitoring usually is recommended to monitor the efficacy of the therapy, especially when the patient is in nonconvulsive status epilepticus.[121,425]

If, after a second attempt, lorazepam fails to control the seizures, intravenous phenytoin (preferably phosphenytoin in children) is the next drug of choice. The dose is 18 to 20 mg/kg, maximum 1000 mg, given over 20 minutes. Phosphenytoin is preferred because it can be administered faster and does not cause sclerosis of the veins as does phenytoin and is not as likely to cause cardiac arrhythmias. Virtually all patients who require

therapy beyond lorazepam need to be intubated to prevent respiratory embarrassment. If phosphenytoin is unsuccessful, or as an alternative to phosphenytoin, intravenous midazolam has gained favor in recent years.[99,336] The initial dose is 0.1 to 0.2 mg/kg over 5 minutes, with a maintenance infusion starting at 0.05 mg/kg/hr up to a maximum of 0.4 mg/kg/hr. Another alternative therapy is propofol, which generally is administered by an anesthesiologist.

Many methods have been proposed to minimize cerebral edema and to diminish the consequences of cerebral anoxia. The following measures are difficult to evaluate and generally are reserved for patients with severe illness whose condition apparently is desperate.

1. Dexamethasone 0.1 to 0.2 mg/kg intravenously in an initial dose followed by 0.05 to 0.1 mg/kg intravenously every 4 to 6 hours is given. This large dose should be reduced gradually after a few days if recovery or improvement is evident. Dexamethasone probably should not be used in acute viral diseases because corticosteroids may potentiate the viral infection.
2. Other substances employed in an effort to reduce elevated intracranial pressure include mannitol, given intravenously as a 20 percent solution in a dose of 0.25 to 1 g/kg over a 30- to 60-minute period (this may be repeated every 8 to 12 hours), and glycerol, given by nasogastric tube using 0.5 to 1 mL/kg diluted with twice that volume of orange juice. This regimen is nontoxic and may be repeated every 6 hours for an extended period.

For more than 40 years, corticosteroids and adrenocorticotropic hormone frequently have been used as empirical therapy for encephalitis. No controlled studies have shown any efficacy, however. In two comparative studies of measles encephalitis, corticosteroids were found to offer no benefit; and in both studies the corticosteroid recipients seemed to have had worse outcomes.[42,467] More recently, in a carefully controlled study, no benefit of high-dose dexamethasone was found in the treatment of acute encephalitis caused by Japanese encephalitis virus.[205]

In contrast to these investigations are more recent clinical experiences in the treatment of acute disseminated encephalomyelitis, in which MRI studies have indicated multifocal white matter lesions.[47,183,240,297] Patients treated with corticosteroids often have responded dramatically, with clinical improvement and resolution of the lesions as shown by MRI. Corticosteroids, along with specific antibiotic therapy, also may be beneficial in the treatment of encephalitis caused by *M. pneumoniae* infection.[248,389]

Plasmapheresis and intravenous immunoglobulin have been used empirically to treat brain stem encephalitis and other encephalitides, but no studies have been done that indicate such therapies are helpful.[320]

Equipment and personnel for handling emergencies such as cardiac and respiratory arrest always must be available. Early consultation with an anesthesiologist or intensive care specialist is useful in anticipating the need for artificially assisted respiration.

Supportive and rehabilitative efforts are important after the patient recovers. Motor incoordination, convulsive disorders, squint, total or partial deafness, or behavioral disturbances may appear only after some time. Visual disturbances caused by chorioretinopathy and perceptual amblyopia also may make a delayed appearance. Special facilities and sometimes institutional placement may become necessary.

PROGNOSIS

The prognosis in all patients with encephalitides is guarded with respect to immediate outcome and sequelae. Sequelae involving the CNS may be intellectual, motor, psychiatric, epileptic, visual, or auditory. The short-term and long-term prognoses depend to some extent on etiology and age. Unfortunately, quality data for most agents are not available, and even less is known about the "unknown" causes.

Rautonen and associates[356] examined prognostic factors in childhood acute encephalitis at the Children's Hospital, University of Helsinki, during a 20-year period from 1968 to 1987. This study comprised 462 cases with the following causes: mumps virus, measles virus, rubella virus, varicella-zoster virus, herpes simplex virus, enteroviruses, respiratory viruses, *M. pneumoniae*, other agents, and cause undetermined. The investigators found that mortality was fivefold greater in infants compared with older children. Children who were disorientated or unconscious before admission had 4-fold and 25-fold greater risks for death and severe damage than did children whose level of consciousness had been normal. Patients with herpes simplex virus or (putative) *M. pneumoniae* infection had the greatest risks for death or serious residual damage compared with children with encephalitis of other causes. Generally, herpes simplex virus carries a worse prognosis for survival and residual disability than do the enteroviruses.

The data on prognosis for arboviruses are more complete than for most other entities owing to the Centers for Disease Control and Prevention's excellent surveillance system. Prognosis of children affected with arboviruses is highly variable. West Nile virus tends to be less severe in children than adults; children accounted for only 4 percent of West Nile neuroinvasive disease in cases reported between 1999 and 2007.[278] There were only 3 fatalities (1%) in the pediatric age group compared with 45 (15%) in adults.[279] Conversely, La Crosse virus (in the California serogroup of viruses) and eastern equine encephalitis are more severe in children than adults.[298] Eastern equine encephalitis has a high mortality rate. Infants and children younger than 5 years of age who survive usually have severe sequelae consisting of mental retardation, convulsions, and paralysis. These consequences are in contrast to adults older than 40 years of age who survive, who recover completely, or have only slight damage.

St. Louis encephalitis has a low mortality rate. Although neurologic sequelae are reported, their incidence is low in the pediatric age group. The prognosis in

encephalitis caused by western equine virus is guarded; 56 percent of infants younger than 1 month of age have had recurring seizures with marked motor and behavioral changes. After they reach 1 year of age, the sequelae appear to diminish; only 5 percent of adults have neurologic sequelae. Fifty-seven percent of infants who survived western equine virus infection and who were younger than 1 year of age at the time of infection had major neurologic sequelae requiring either a special school or institutionalization late in life. Severe retardation, paralysis, spasticity, recurrent convulsions, hearing deficits, and speech difficulties all were reported as complications.[133,143]

Nevertheless, progress has been made recently for some causative agents that were thought to always have a poor outcome, and the paradigm seems to be changing. For example, rabies previously was considered to be universally fatal, but in 2004 a 15-year-old girl in Wisconsin developed rabies and survived, representing the first person to survive documented clinical rabies without previous vaccination.[455] Since then, two additional human rabies cases have occurred in the United States and both patients survived without significant neurologic sequelae.[79,82]

Correspondingly, *B. mandrillaris* encephalitis was also considered to have a grave prognosis but recent case reports described successful outcomes.[58,117] Similarly, all previously reported human cases of *Baylisascaris* meningoencephalitis had resulted in either severe neurologic sequelae or death; in 2007, a case report was published concerning a 4-year-old child with *Baylisascaris* meningoencephalitis who survived without any recognizable neurologic deficits.[332]

PREVENTION

The widespread use of effective attenuated viral vaccines for measles, mumps, and rubella almost has eliminated CNS complications from these diseases in the United States. The control of encephalitis caused by arboviruses is primarily through control of insect vectors. Specific vaccines for the arbovirus diseases that occur in North America are unavailable. Until we learn more about the "unknowns," it will be difficult to know how to prevent many of the causes.

CHAPTER 37

Parainfectious and Postinfectious Disorders of the Nervous System

37A ■ PARAINFECTIOUS AND POSTINFECTIOUS DEMYELINATING DISORDERS OF THE CENTRAL NERVOUS SYSTEM

J. Lloyd Holder, Jr. • Timothy E. Lotze

ACUTE DISSEMINATED ENCEPHALOMYELITIS

Acute disseminated encephalomyelitis (ADEM) is a monophasic demyelinating disease of the central nervous system (CNS) that results in acute, polysymptomatic neurologic disability. It also has been termed *postinfectious encephalomyelitis*. It is related to other central inflammatory demyelinating conditions of childhood, including optic neuritis, transverse myelitis, neuromyelitis optica (Devic disease), and multiple sclerosis. Although no single diagnostic test can be used to distinguish among these conditions at the initial presentation, certain clinical features, laboratory results, and imaging findings can be used to ensure a correct diagnosis. Most of these conditions are thought to be caused by autoimmune dysregulation triggered by an infectious agent in a genetically susceptible host.

EPIDEMIOLOGY

The estimated incidence of ADEM is 0.8/100,000 population per year.[37] ADEM occurs just as frequently in children as it does in adults.[11] It has no specific gender predilection or ethnic distribution.[14,15] In contrast to multiple sclerosis, which generally has a higher incidence at more northern latitudes, ADEM has no appreciable geographic distribution.

DIAGNOSTIC CRITERIA

The term *acute disseminated encephalomyelitis* has been used variably in the literature in describing clinical characteristics of this disease. Discrepancies exist among descriptive studies regarding (1) the occurrence of encephalopathy, (2) the association with preceding infection, (3) symptoms that are monofocal or multifocal, and (4) the possibility for recurrence. Lack of standardized diagnostic criteria for ADEM has impeded the ability to understand this distinct disease better as part of the spectrum of demyelinating conditions occurring in childhood.

The International Pediatric Multiple Sclerosis Study Group developed diagnostic criteria for ADEM.[35] The group created working definitions for monophasic ADEM and for recurrent forms of the disease. Table 37A-1 lists the diagnostic criteria. An absolute criterion for a diagnosis of ADEM is the presence of encephalopathy. This criterion is defined to include either behavioral changes, such as lethargy or irritability, or more severe alterations in level of consciousness, such as coma. The onset of the encephalopathy must correspond with the occurrence of the disease state. Premorbid cognitive difficulties, such as learning difficulties or mental retardation, would not be included in this definition. Magnetic resonance imaging (MRI) shows multiple lesions in both hemispheres distributed throughout the white matter (Fig. 37A-1). A distinguishing characteristic of ADEM is prominent involvement of the cortical gray matter and deep gray nuclei (basal ganglia and thalamus). Such involvement is atypical for multiple sclerosis and other demyelinating conditions. The lesions of ADEM are asymmetric, showing variable size, shape, and distribution between the hemispheres. MRI showing symmetric and confluent lesions should prompt the clinician to consider other diagnoses, such as leukodystrophies and inborn errors of metabolism. If MRI shows evidence of previous demyelination, the clinician should query the history further for previous attacks, which would suggest either a recurrent form of the disease or a chronic demyelinating condition. Cerebrospinal fluid (CSF) analysis may show a pleocytosis of greater than 50 cells, in contrast to pediatric multiple sclerosis, in which only a slight pleocytosis (<50 cells) is observed.

TABLE 37A-1 Diagnostic Criteria of Acute Disseminated Encephalomyelitis

Clinical Features
First clinical attack of demyelinating disease in CNS
Acute or subacute onset
Polysymptomatic presentation
Must include encephalopathy Acute behavioral change (e.g., irritability, lethargy) Alteration in consciousness (e.g., somnolence, coma)
Attack should be followed by improvement
Lesion Characteristics on MRI FLAIR and T2-Weighted Images
Multifocal, hyperintense, bilateral, asymmetric lesions in the white matter
At least one or more lesions >1-2 cm
Gray matter, especially basal ganglia and thalamus, may be involved
Spinal cord MRI may show confluent intramedullary lesions
No radiologic evidence of previous destructive white matter changes
Cerebrospinal Fluid
Pleocytosis ≥50 WBCs can be observed
Other
No other etiologies can explain the event
New or fluctuating symptoms and signs occurring within 3 mo of the inciting ADEM event are part of the same acute event

Note: Symptoms that vary during periods of steroid taper within 3 mo of the inciting event or occur <30 days after discontinuation of all steroids are considered part of the initial inciting event.

ADEM, Acute disseminated encephalomyelitis; *CNS,* central nervous system; *FLAIR,* fluid-attenuated inversion recovery; *MRI,* magnetic resonance imaging; *WBCs,* white blood cells.

The International Pediatric Multiple Sclerosis Study Group has defined criteria to distinguish between an evolving pattern for the initial event and recurrent forms of ADEM. Any new and fluctuating symptoms occurring within 3 months of the initial event are considered part of the same inciting event. In addition, symptoms occurring during steroid taper or within 1 month of the patient completing a steroid taper are considered part of the same inciting event. Relapsing ADEM and multiphasic ADEM are the two recurrent forms of the disease. Both forms are defined to occur more than 3 months after the initial event and more than 1 month after completion of steroids. By definition for ADEM, both forms must include a clinical presentation with encephalopathy. Relapsing ADEM describes the recurrence of the same symptoms that occurred at the time of the initial presentation. The MRI findings also are similar to the initial event, although they may show enlargement of the previous lesions. Multiphasic ADEM describes children with recurrent disease characterized by symptoms that differ from those of the initial event. MRI likewise shows development of new lesions different from those seen with the first attack.

CLINICAL MANIFESTATIONS

A febrile illness occurs in 50 to 75 percent of children in the 4 weeks before the onset of typical neurologic symptoms.[41] Preceding vaccinations have been associated with the occurrence of ADEM, but this is less common.[15,51] Fever, headache, vomiting, and meningismus often are present at the time of initial presentation and may persist during the hospitalization.[9,24] Neurologic symptoms typically appear 4 to 13 days after the infection develops or vaccination is administered.[15,24,43,51] New clinical symptoms may continue during hospitalization and may alter treatment. Per current diagnostic criteria, all children with ADEM have an encephalopathy at the time of presentation.[35] The degree of altered mental status varies, ranging from irritability to somnolence to coma. Encephalopathy may be the initial symptom that brings the child to medical attention. Although alteration in mental state often raises concern for the possibility of seizures, they occur in only one third of patients.[16,51] In addition to having encephalopathy, patients exhibit various other neurologic features. The most common of these are long tract signs, acute hemiparesis, cerebellar ataxia, and cranial neuropathy.[9,16,25,43,51] Aphasia, movement disorders, and sensory deficits occur less commonly.

Demyelination of the optic nerves (optic neuritis) or spinal cord (transverse myelitis) may occur. Symptoms of optic neuritis include vision loss, pain with eye movement, and an afferent papillary defect. Inflammation of the optic disk may be seen on direct funduscopic examination if there is extensive involvement of the optic nerve. Patients with retrobulbar optic neuritis typically have a normal funduscopic examination. Optic neuritis may occur in one or both eyes, with differing degrees of involvement. Symptoms of transverse myelitis include flaccid paralysis of the legs, with a sensory level on examination. The arms can be involved as well if the demyelinating lesion is in the cervical cord. Respiratory failure may occur with high cervical lesions that extend into the brain stem. Bowel and bladder involvement secondary to spinal cord disease results in constipation and urinary retention.

The extent of demyelination in the CNS may not be recognized fully at the time of initial presentation, particularly if the patient has severe encephalopathy. Imaging of the entire CNS to include the brain, orbits, and spinal cord should be done in all patients meeting diagnostic criteria for ADEM because co-occurrence of transverse myelitis or optic neuritis can have a significant impact on rehabilitation needs and long-term outcome.

CLINICAL VARIANTS

Relapsing ADEM and multiphasic ADEM are the two recurrent forms of the disease. Both forms are defined by reoccurrence of neurologic symptoms more than 3 months after the initial event and more than 1 month after completion of steroids. Most often, recurrence of disease is singular. Repeated events are unusual and should prompt assessment for a different underlying

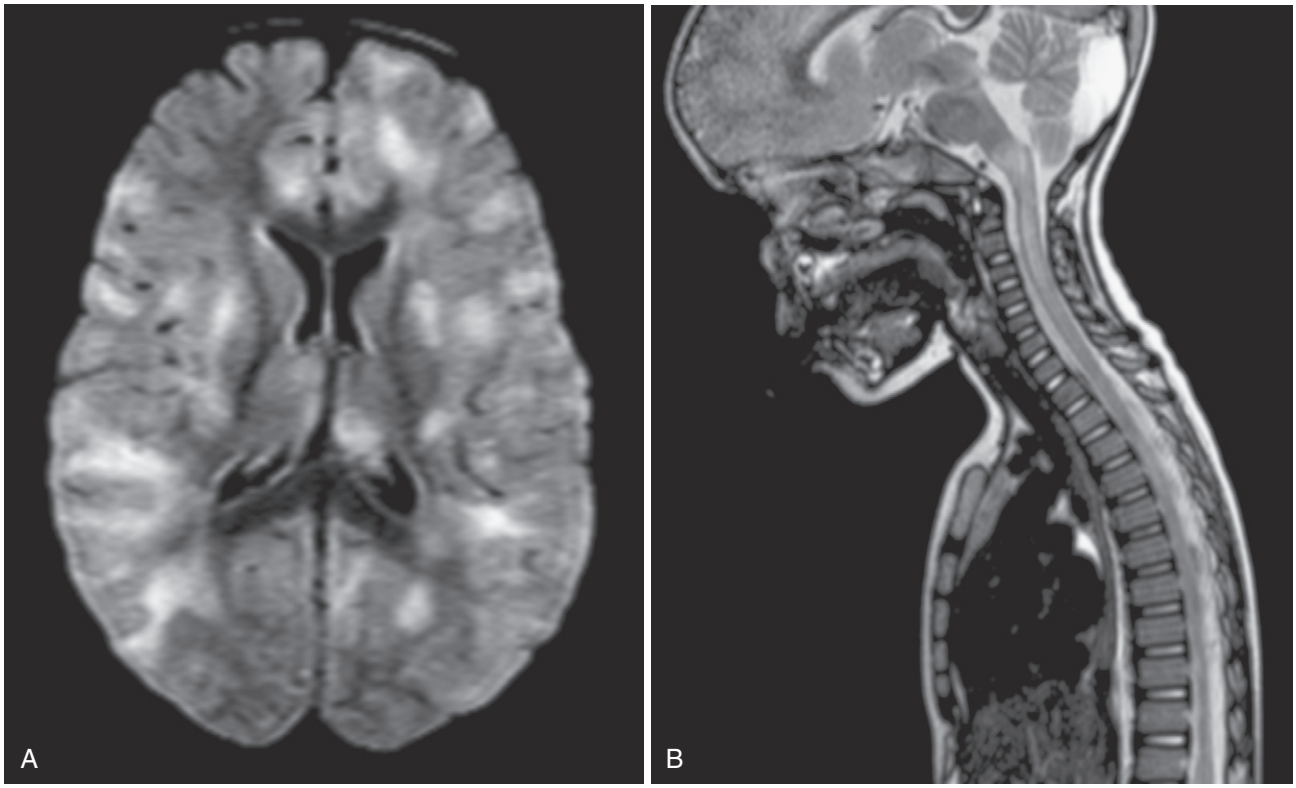

FIGURE 37A-1 ■ **A,** Axial fluid-attenuated inversion recovery (FLAIR) image showing multifocal areas of hyperintensity in both cerebral hemispheres involving cortical gray matter, centrum semiovale, and deep gray nuclei. **B,** Sagittal T2-weighted spine image with increased intrinsic signal consistent with longitudinally extensive transverse myelitis in the same patient. disease process, including metabolic disorders or primary inflammatory diseases such as multiple sclerosis.

Acute hemorrhagic leukoencephalitis is considered a severe variant of ADEM. It accounts for 2 percent of patients with ADEM.[51] Clinical presentation is similar to that of ADEM, including an acute onset of neurologic deficits 1 to 3 weeks after an upper respiratory tract infection or vaccination. Seizures and coma ensue within hours. The mortality rate is extremely high with fulminant disease. Survivors often have severe residual neurologic deficits. The clinical presentation and imaging features mimic those typically seen in herpes simplex virus encephalitis. Evidence of inflammatory changes and hemorrhage on MRI often is not present for the first few days in herpes simplex virus encephalitis, which may help distinguish the two conditions.[20] Early recognition with prompt institution of steroids or other immunosuppressive agents can be lifesaving.

Historically, site-restricted forms of demyelination, such as optic neuritis or transverse myelitis, have been included as part of the spectrum of ADEM. Although these conditions share similar underlying pathology, clinical presentations and prognosis are different, and they should be considered to be separate entities. They are considered clinically isolated syndromes by the current consensus definitions for demyelinating disease.[35] Clinically isolated syndromes may carry a greater risk for development of multiple sclerosis or other recurrent forms of demyelinating disease.[53] *Neuromyelitis optica*, also known as *Devic disease*, describes coincident or sequential optic neuritis and longitudinally extensive myelitis. It is not always peri-infectious in onset and is associated with antibodies directed against aquaporin-4 water channels in the CNS.[54]

Multiple sclerosis is the second most common cause of acquired neurologic disability in adults. It is an uncommon finding in pediatric patients. Five percent of adults with multiple sclerosis had onset of disease before reaching 18 years of age.[5] Clinical phenotypes consistent with ADEM, relapsing ADEM, and multiphasic ADEM should not be confused with multiple sclerosis. Although they may share some of the same initiating pathologic mechanisms, they are different diseases.[11] The diagnosis of multiple sclerosis requires clinical or radiographic evidence for demyelinating events separated in space and time in the CNS. Patients typically follow a relapsing course of neurologic attacks, with resolution or remission of disability between attacks. Evolution into a course of progressive disability occurs in 50 percent of patients who have had the disease for more than 15 years.[8] Treatment consists of medications that modulate the immune response by decreasing migration into the CNS, altering cytokine profiles, and interrupting antigen presentation.

PATHOLOGY AND PATHOGENESIS

Role of Infection

ADEM is preceded by a viral or bacterial infection in 75 percent of the cases. This infection usually is in the form of a nonspecific upper respiratory tract infection. Many

different pathogens have been identified in association with the illness (Table 37A-2). No well-defined latency period has been identified in which an infection can be related to ADEM. Generally, patients present within 1 month of their illness. Correlation between ADEM and an infection occurring more than 30 days before is more difficult because children are diagnosed with a viral infection four to six times per year, resulting in a positive infectious history in 33 to 50 percent of patients.[41]

The phenotypic presentation for ADEM varies depending on the infectious agent. Some organisms have been associated with typical clinical features. Measles virus infection is associated with ADEM in 1/1000 cases. The clinical course often is fulminating, with severe neurologic sequelae or death in most patients. Introduction of vaccination has reduced markedly the occurrence of measles in developed countries, although vaccine-associated ADEM is described in 2 cases per 1 million.[7]

Postvaricella ADEM is characterized by ataxia in more than 90 percent of patients, occasionally with an explosive onset.[26] Headache and meningismus are typical constitutional signs. Pyramidal symptoms include bilateral symmetric upper motor neuron weakness. Patients also may have mood disturbances with a depressed affect or irritability.

ADEM that develops after a rubella infection is similar to measles, with an explosive onset in most children.[26] Profound lethargy, coma, and generalized seizures often occur. Most patients with explosive onset of disease have pyramidal signs and myelitis, whereas a milder phenotype is more likely to have ataxia. Both forms also have been associated with brain stem signs.

Group A β-hemolytic streptococcal infection has been associated with a dystonic extrapyramidal syndrome. Abnormal movements include dystonia, tremor, and parkinsonism. Tics and chorea have not been associated with this condition. Similar to Sydenham chorea and PANDAS, behavioral disturbances, such as emotional lability, obsessive-compulsive tendencies, and inappropriate speech, can occur. Changes in mental status can vary from irritability to coma. MRI shows a predilection for demyelination within the basal ganglia, which includes the caudate, putamen, and globus pallidus. Other deep gray structures, including the thalamus, subthalamus, and substantia nigra, may be affected as well. This finding is distinct from Sydenham chorea and PANDAS, in which imaging is unremarkable. It has been associated with anti–basal ganglia antibodies that cross-react with certain strains of streptococcus.[14]

Role of Immunization

Vaccine-associated ADEM has been described with nearly every immunization (Table 37A-3). The Collaborating Center for Reference and Research on Viral Hepatitis of the World Health Organization has suggested a maximal period of 3 months to diagnose vaccination-associated ADEM. Postvaccination ADEM accounts for fewer than 5 percent of ADEM cases.

Historically, Pasteur rabies vaccination was associated with prototypic ADEM in approximately 1/1000 individuals.[7] The inoculum was derived from rabbit spinal cord injected with fixed rabies virus. The disease was thought to result principally from the neural tissue contaminating the vaccine, rather than the virus itself. This suggestion is supported further by the continued higher incidence of vaccine-associated encephalomyelitis in patients receiving the Semple or duck embryo vaccinations, both of which contain neural tissue. These forms of the vaccination usually are found in developing countries. Experimental allergic encephalomyelitis, the animal model of demyelinating disease, is induced by inoculating myelin or myelin antigens into a suitable experimental animal, further supporting a role of CNS tissue as the causal agent.

Currently, measles, mumps, and rubella vaccination is associated most often with postvaccination encephalomyelitis. A significant difference exists between the incidence of live-measles vaccination associated ADEM (1 to 2/1 million) and the incidence of ADEM previously associated with the measles virus infection (1/1000).

Smallpox was eradicated in 1980 after a successful vaccination program that was discontinued in the United States in 1971.[12] The World Health Organization has allowed retention of the variola virus at a designated laboratory in the United States and Russia for the purpose of creating a safer vaccination than the presently available live vaccinia virus. More recent concerns for bioterrorism have resulted in the reinstitution of smallpox vaccination to certain identified groups within the United States that might come into contact with the virus as first responders to a possible smallpox outbreak. The previously reported incidence of ADEM associated with smallpox vaccination was 10 to 300 cases for every 1 million vaccinations. It is estimated, based on these figures, that vaccination of the entire British population would result in approximately 600 cases of vaccine-associated ADEM. Administration of antivaccinia gamma globulin at the time of vaccination can help prevent this complication.[48]

Immunologic Factors

A review of the normal process of immune system regulation and surveillance of the CNS is useful when discussing immune dysfunction in the pathogenesis of ADEM. Similar to other disorders of immune dysfunction, activated $CD4^+$ T cells play a principal role in the disease process. T cells reactive against self-antigens, including myelin components, are present in the normal immune system. Several regulatory mechanisms are thought to prevent activation of these lymphocytes, and failure of such processes results in autoimmune conditions. The thymus plays a crucial role in normal T-cell development by deleting many autoreactive lymphocytes from the immune system. Other peripheral mechanisms also are needed because this thymic depletion often is incomplete. Clonal anergy describes the unresponsive state of T cells that have encountered their antigen without costimulatory factors.[44] A risk for failure of this mechanism exists through release of nonspecific, costimulatory factors from damaged tissue. Another peripheral process is immunologic ignorance, in which no productive reaction exists between the T cell and its corresponding peptide/major histocompatibility complex on an antigen-presenting cell. Changes in antigen availability, such as through increased antigen presentation by an invading microorganism, can disrupt this safeguard.[28]

Active regulation is a third process by which regulatory T cells prevent expansion of self-reactive lymphocytes.[34] Regulatory T cells exert their suppressive effects through direct cell-to-cell contact with membrane-bound molecules (CTLA-4) or indirectly through soluble suppressive cytokines, such as interleukin (IL)-10 and transforming growth factor-β (TGF-β).[27] Natural killer cells expressing a T-cell receptor also can regulate autoimmune diseases.[40] The presence of such cells within demyelinating regions suggests that some of the inflammation associated with ADEM may have a protective effect.

Although failure of these mechanisms may result in the activation of T cells reactive against myelin antigens, migration of lymphocytes into the CNS is required to produce disease. The CNS has been considered a site of limited immunologic surveillance because of the blood-brain barrier and lack of classic lymph vessels. The blood-brain barrier is principally a mechanical diffusion barrier, however, for hydrophilic molecules formed by specialized endothelial cells at the level of the capillaries. Leukocytes readily cross through endothelial cells in postcapillary venules to occupy the perivenular spaces or move on to the neuropil.[23] In addition, antigens and antigen-presenting cells drain from the brain into cervical lymph nodes via the cribriform plate and perineural sheath of the cranial nerves.[13,30] As discussed later, these factors allow for the presentation of antigen in the systemic immune compartment and passage of leukocytes into the CNS for production of disease.

Children with demyelinating disease of the CNS are thought to have a genetic predisposition for such conditions. The strongest data relate to susceptibility genes on chromosome 6p21 in the area of the histocompatibility leukocyte antigen (HLA). Much of the research into these genetic determinants has been related to adult-onset multiple sclerosis.[50] Limited research is available for pediatric demyelinating diseases. Some of the findings show similarities, however, among age groups and various demyelinating diseases. Linkage studies in Russian children found an association between ADEM and *HLA-DRB1*01* and *HLA-DRB1*017(03)* alleles.[26] Korean children with ADEM were found to have higher frequencies of *HLA-DRB4*0101* and *HLA-DRB1*1501* compared with controls. In adults with multiple sclerosis, the specific genes that confer the highest risk include *HLA-DRB1*1501* and *HLA-DRB5*0101* among others. In multiple sclerosis, these genes have been linked to earlier disease onset, female gender, a relapsing remitting course, and optic neuritis or spinal involvement as the initial symptom. In addition, genes associated with this haplotype include TGF-β family members, CTLA-4, the tumor necrosis factor cluster, IL-1 receptor antagonist, IL-1, and estrogen receptor. Polymorphisms in these genes also have been associated with increased risk for development of demyelinating disease.[18]

The precise mechanism by which these HLA class II genes confer risk for development of demyelinating disease is unclear. Possibilities include (1) preferential binding of self-antigens by these peptides, (2) preferential linkage of autoreactive T cells to the antigen-presenting cell expressing these peptides, (3) abnormal antigen presentation by certain DR molecules, and (4) engagement of HLA class II molecules leading to intracellular signaling events.[50]

Humoral factors also play a role in the production of demyelinating disease. This finding is based on disease-associated laboratory findings and treatment responses. Analysis of CSF in one third of patients with ADEM shows production of oligoclonal bands, which are not found in the serum.[15] In addition, some patients with

post–rabies inoculation ADEM have been found to have positive serum antibodies against myelin basic protein and galactocerebroside.[36]

Pathogenesis

ADEM is considered to occur in genetically susceptible individuals prone to immune system dysregulation after an encounter with an appropriate environmental stimulus. Mechanisms of disease production are based principally on two animal models that closely resemble the disease. The first is experimental autoimmune encephalomyelitis.[47] In this model, animals develop monophasic neurologic disease similar to ADEM after receiving immunization with CNS homogenate or encephalitogenic myelin peptides emulsified in Freund complete adjuvant. The second model is Theiler murine encephalomyelitis, in which susceptible mouse strains develop disease after receiving direct injection of Theiler murine encephalomyelitis virus into the cerebrum.[24] In both of these models, increased exposure of the immune system to myelin proteins produces disease.

By comparing these models with ADEM in humans, two pathogenetic concepts have been developed. The inflammatory cascade concept implies a direct CNS infection with a neurotropic pathogen, which results in CNS tissue damage and systemic leakage of CNS-confined autoantigens through a damaged blood-brain barrier into the systemic circulation. Presentation of these antigens within systemic lymphatic organs leads to tolerance breakdown and a self-reactive encephalitogenic T-cell response. The molecular mimicry concept suggests structural amino acid homology between the invading pathogen and myelin basic protein in the host.[19] Although similar to myelin peptides, the amino acid sequence contains subtle differences that fail to prevent immune tolerance and result in activation of myelin-reactive T cells against similar "self" myelin antigens. The Epstein-Barr virus provides an example of this. The virus contains a pentapeptide sequence in its nuclear antigen (EBNA) that shares sequence homology with an epitope of myelin basic protein, a major protein of the myelin sheath.[10] Epstein-Barr virus has been implicated in the pathogenesis of multiple sclerosis partly based on this concept of molecular mimicry.[2] Recently, antibodies to myelin oligodendrocyte glycoprotein have been shown to be present during the period of active demyelination in ADEM but quickly fall in most patients.[46] In those with persistent or rebounding of myelin oligodendrocyte glycoprotein antibody levels, a propensity was seen to develop childhood multiple sclerosis, suggesting this might be prognostic.

The immunopathologic events leading to ADEM can be divided into two major phases: (1) initial T-cell priming and activation and (2) subsequent recruitment and effector phase.[6] The priming phase occurs in systemic secondary lymphoid organs, in which the antigen-presenting cell presents myelin protein antigen and peptides to neuroantigen-reactive T cells. The activated T cells expand and then migrate to the CNS via the postcapillary venules into the perivascular space. In the Virchow-Robin space, the T cells re-encounter their cognate antigen, in the context of HLA class II molecules expressed by dendritic cells.[21] This reactivation allows the T cells to migrate through the glial limitans and enter the brain parenchyma.

Further recruitment occurs through the production of cytokines and chemokines by antigen-presenting cells and activated T cells, promoting migration into the CNS of additional T cells and other leukocytes, such as polymorphonuclear and monomorphonuclear phagocytes.[50] Breakdown of the blood-brain barrier occurs by release of proteases from recruited mast cells, T cells, and monocytes. In addition, production of reactive oxygen radicals occurs, causing further endothelial injury, which leads to the effector phase in which T cells have more of a secondary role to other inflammatory processes that cause demyelination and axonal injury. These inflammatory processes include oxygen and nitrogen radicals, tumor necrosis factor-α, direct and indirect complement activation, antibody-dependent cellular toxicity, myelin phagocytosis, direct axonal injury by $CD8^+$ cytotoxic T lymphocytes, protease secretion, and oligodendrocyte apoptosis.[50] Glutamate-mediated excitotoxic injury of the oligodendrocytes also occurs.[45] The inflammatory process continues for a few days to 2 weeks, resulting in stretches of demyelinated axons, some of which may be transected.

The repair process begins with activation and proliferation of astrocytes. Clearing of debris by macrophages and increased production of anti-inflammatory cytokines and various growth factors by resident cells and T cells occur. Oligodendrocyte precursors become activated and, along with surviving oligodendrocytes, begin the process of remyelination. The clinical and imaging outcome of ADEM most often shows complete recovery. Subtle differences in repaired myelin, including altered thickness and redistribution of sodium channels, may occur, however.[52] In addition, the relative composition of myelin peptides is altered to forms that may have increased vulnerability to further damage[48] and may explain recurrent forms of ADEM.

CLINICAL EVALUATION

ADEM should be considered in a child seen several days after a febrile illness with subacute onset of encephalopathy and polysymptomatic neurologic deficits. The clinical features require ruling out other possible diagnoses, however, through additional diagnostic tests.

Diagnostic imaging is the most useful tool in establishing the diagnosis. Computed tomography (CT) scans usually are done on an emergent basis for encephalopathic patients. Areas of demyelination may appear as darker areas of hypodensity, with any hemorrhagic component being hyperdense. CT does not adequately show the full burden of disease, however, and may be completely normal. MRI is the most sensitive means for showing the widespread demyelination typical of the disease (see Fig. 37A-1). T2-weighted sequences provide the best assessment of the disease, with demyelinating areas being hyperintense and accompanied by surrounding edema. Administration of gadolinium contrast

material may show breakdown of the blood-brain barrier with areas of enhancement. This enhancement may appear homogeneous throughout the lesion or show a "broken ring" appearance, with the open edge pointing toward the cortex. Lesions may be large, measuring more than 1 cm in diameter. They typically are rounded with poorly defined margins.

Of most common concern in children presenting with a febrile encephalopathy is the possibility of an underlying CNS infection. A lumbar puncture often is done to investigate this possibility. A lymphocytic pleocytosis may occur (commonly >50 cells). Elevated albumin levels also may be present. Findings of neutrophils and elevated red blood cells alternatively would raise concern for the possibility of herpes encephalitis.

Intrathecal oligoclonal bands may be positive, and IgG synthesis may be increased in 30 percent of patients with ADEM. These abnormalities usually are associated with multiple sclerosis. In ADEM, convalescent testing for both should normalize, whereas tests remain positive in multiple sclerosis. Their relationship to the underlying disease pathophysiology is unclear but is thought to represent a response of B cells within the CNS to the inflammatory process.[3] Serologic studies of the CSF may be useful to uncover the causal agent, although results should be interpreted with caution because many neurotropic viruses have a high prevalence in the general population.

Rarely, patients may present with very large demyelinating lesions, characteristically described as *tumefactive*. In such circumstances, a biopsy may be needed to determine the underlying etiology. Findings typical of demyelination help rule out a CNS malignancy. Before a biopsy is done, the clinician should investigate for other evidence of demyelinating disease, including imaging of the spinal cord. A comorbid transverse myelitis would provide more evidence of a demyelinating condition and reduce the need for a biopsy. In addition, normal CSF cytology helps discount an underlying malignancy.

Primary and secondary CNS vasculitis associated with collagen vascular diseases, such as systemic lupus erythematosus or antiphospholipid antibody syndrome, may manifest with a similar clinical and radiologic picture. These diseases are typified by recurrent ischemic strokes. Distinguishing features for antiphospholipid antibody syndrome include a family history of strokes or other thromboses at a young age and fetal loss. Testing for antiphospholipid antibody and lupus anticoagulant is positive. Primary CNS vasculitis with strokes is best investigated through conventional angiography showing an irregular vessel lumen. Leptomeningeal biopsy is considered the gold standard to confirm the diagnosis.

A severe course that principally affects the optic nerves and spinal cord should raise concern for neuromyelitis optica. Serum or CSF testing for the aquaporin-4 water channel antibody that is associated with this disease is clinically available. The test is greater than 90 percent specific for neuromyelitis optica.[34]

Neurophysiologic studies can be useful to evaluate comorbidities and burden of disease. An electroencephalogram should be obtained in patients with seizures and severe encephalopathy to characterize the seizure focus and investigate for subclinical seizures. Findings often are consistent with a diffuse disturbance in brain function noting slowing of the normal electric rhythms. Visual evoked potentials can evaluate for demyelination of the optic nerves, which may not be appreciated on imaging. The examination measures the time for an electric impulse to travel from the retina to the occipital lobe, with delays suggesting a demyelinating lesion. The patient needs to be attentive to a flashing light stimulus, rendering this test difficult to perform in patients with severe encephalopathy.

TREATMENT

To date, no controlled clinical trials have been conducted regarding the optimal treatment for ADEM. Based on empirical evidence, intravenous high-dose corticosteroids are accepted as first-line treatment.[49] Methylprednisolone is given at 30 mg/kg per dose (maximum 1000 mg) for a total of five doses. Alternatively, dexamethasone, 1 mg/kg per dose for five doses, may be used. A prednisone taper typically is instituted on completion of this regimen, with an initial dosing of 1 mg/kg/day and tapering by 5 mg every 5 days. Alternative anti-inflammatory and immunosuppressive therapies may be used depending on the response to the initial steroid treatment. Intravenous immunoglobulin (IVIG) has been found to be beneficial in some patients.[49] IVIG is given 2 g/kg divided over 2 to 5 days.

Plasmapheresis also may be used.[31,33] The patient receives a total of seven treatments consisting of 1.1 to 1.4 plasma volume exchanges over a 14-day course. IVIG and plasmapheresis typically are not considered as first-line treatment for ADEM, partly related to availability of IVIG or pheresis units, cost of treatment in contrast to steroids, prolonged hospitalization, and need for adequate venous access. Nonetheless, they should be considered secondary treatment options, especially in the occasional patient who continues to deteriorate during steroid treatment or who fails to show adequate recovery 7 days after completing intravenous steroids. The choice between the two agents is arbitrary. Particular consideration for plasmapheresis might be given in the setting of a comorbid myelopathy because this has been noted to be beneficial in patients presenting with transverse myelitis.[29] Severe cases failing to respond to any of these measures may require immunosuppressive agents, such as cyclophosphamide.[39] A few cases of severe ADEM with massive edema have required hemicraniectomy to prevent severe neurologic sequelae or death.[1,17]

Additional treatment that may be needed depends on the patient's neurologic deficits. Anticonvulsants should be given for management of seizures. Attention given to bowel and bladder care is important to avoid secondary complications of retention. Impaired swallowing requires adequate nutrition to be provided by gavage feedings. Transverse myelopathy can be associated with autonomic dysfunction, including orthostatic hypotension, necessitating the use of an abdominal binder. Rehabilitation should begin at the time of admission, with the assistance of physical medicine and rehabilitation specialists. During

the long-term recovery period, modifications to the home and school environment may be needed, depending on residual deficits.

OUTCOME AND PROGNOSIS

Historically, ADEM was associated with high morbidity and mortality rates principally related to disease associated with the measles virus. Measles-associated ADEM was associated with death in 25 percent of affected patients, with an additional 30 percent of patients having severe neurologic sequelae.[38] This dismal outcome has improved dramatically with institution of measles vaccination. The introduction of high-dose steroid treatment in modifying the disease course also may have improved the current outcome findings. A 5 percent mortality rate remains associated with this disease.

Currently, 80 to 90 percent of patients show excellent recovery of functional and cognitive deficits.[4,15,26,51] Children typically have a less severe course and fewer long-term neurologic sequelae than adults.[32] Mild neurologic disabilities, with weakness and fine motor difficulties being the most common deficits, may be present in some patients. Epilepsy may occur in 6 percent of patients after an episode of ADEM.[15] Neurocognitive testing of children recovering from ADEM has shown mild impairments in attention and executive function and reduced visuospatial and visuomotor skills.[22] The greatest risk for development of neurologic sequelae may be in older patients with sudden onset of severe neurologic symptoms.

Recurrent forms of the disease often raise concern for pediatric multiple sclerosis. The exact relationship between ADEM and multiple sclerosis remains to be better defined. The conditions are distinct, however, based on the clinical presentations, imaging, and clinical courses. Studies investigating risk for disease recurrence or evolution into multiple sclerosis have been limited and do not adequately define ADEM in the context of the current definition, and they do not distinguish between recurrent forms of the disease and multiple sclerosis. Disease recurrence occurs in 30 percent of patients.[41] Most patients have their second attack within the first year after their initial event.[4,42] It often occurs soon after discontinuation of steroid taper, or after an infection or vaccination encountered shortly after the initial event. Treatment and outcome for recurrences are not different from those described for the initial event.

37B INFECTION-ASSOCIATED MYELITIS AND MYELOPATHIES OF THE SPINAL CORD

J. Lloyd Holder, Jr. • Timothy E. Lotze

ACUTE TRANSVERSE MYELITIS

The sudden and progressive onset of paresis, sensory deficits and bowel and bladder dysfunction that characterizes acute transverse myelitis (ATM) terrifies affected children and their families. Successful management requires prompt differentiation from other myelopathic disorders to determine proper treatment. Because of the association of ATM with numerous infections, specialists in infectious diseases frequently participate in the care of children with ATM. The clinical presentation, radiologic features, differential diagnosis, pathophysiology, treatment, and prognosis of pediatric ATM are reviewed here.

DIAGNOSTIC CRITERIA

ATM is an acquired demyelinating disorder consisting of progressive signs and symptoms reflecting bilateral sensory, motor, or autonomic dysfunction attributable to the spinal cord. This constellation of signs and symptoms can be caused by a heterogeneous group of disorders, including ATM. Several disorders, including direct infections of the spinal cord, can mimic ATM.

Diagnostic criteria were established by the Transverse Myelitis Working Group Consortium in 2002 and consist of both inclusionary and exclusionary criteria. The criteria were established to rapidly differentiate ATM from other myelopathies that require different treatment regimens. Differentiation from extramedullary compression such as that caused by extrinsic tumor, abscess, hematoma, and other intramedullary lesions such as infarction and intrinsic tumors are necessary to guide treatment and facilitate discussion of prognosis. Table 37B-1 lists both the inclusionary and exclusionary criteria for ATM.

TABLE 37B-1 **Transverse Myelitis Consortium Working Group Diagnostic Criteria**

Inclusion Criteria	Exclusion Criteria
Bilateral signs/symptoms (not necessarily symmetric)	Clear arterial distribution clinical deficit consistent with thrombosis of anterior spinal artery
Clearly defined sensory level	Abnormal flow voids on surface of the spinal cord consistent with AVM
Exclusion of extra-axial compressive etiology by neuroimaging (MRI or myelography; CT of spine inadequate)	Serologic or clinical evidence of connective tissue disease (sarcoidosis, Behçet disease, Sjögren syndrome, SLE, mixed connective tissue disorder)*
Inflammation within spinal cord shown by CSF pleocytosis or elevated IgG index or gadolinium enhancement. If no inflammatory criteria are met at symptom onset, repeat MRI and lumbar puncture evaluation 2-7 days after symptom onset meet criteria	CNS manifestations of syphilis, Lyme disease, HIV, HTLV-1, *Mycoplasma,* other viral infection (e.g., HSV-1, HSV-2, VZV, EBV, CMV, HHV-6, enteroviruses)* Brain MRI abnormalities suggestive of MS* History of clinically apparent optic neuritis*
Progression to nadir 4 hr to 21 days after onset of symptoms (if patient awakens with symptoms, symptoms must become more pronounced from point of awakening)	

Data from Transverse Myelitis Working Group. Proposed diagnostic criteria and nosology of acute myelitis. *Neurology* 2002;**59**:499–505.

*Do not exclude disease-associated acute transverse myelitis.

AVM, Arteriovenous malformation; *CMV,* cytomegalovirus; *CNS,* central nervous system; *CSF,* cerebrospinal fluid; *CT,* computed tomography; *EBV,* Epstein-Barr virus; *HIV,* human immunodeficiency virus; *HHV-6,* human herpesvirus-6; *HSV,* herpes simplex virus; *HTLV-1,* human T-cell lymphotrophic virus-1; *MRI,* magnetic resonance imaging; *MS,* multiple sclerosis; *SLE,* systemic lupus erythematosus; *VZV,* varicella-zoster virus.

EPIDEMIOLOGY

Two prospective studies have evaluated the incidence of acquired ATM in children.[7,16] Based on these studies, the incidence in pediatric populations is approximately 1.72 to 2 persons per 1 million. Although early case series had suggested a slight female predominance,[14,15,20,37,56,58] the more recent prospective studies have found a male predominance in the pediatric population. When stratifying for children younger than 10 years of age at onset and older than 10 years of age, one study found a striking 1:2 female to male ratio in children younger than 10 years old. In children with age of onset older than 10 years, the female to male ratio was 1.2:1, similar to those of other inflammatory demyelinating disorders.[7] The mean age of onset is between 9 and 10.5 years; however, onset has been reported as early as 6 months. Of interest, one study found a bimodal distribution with peak ages of onset at 4 and 15 years.[16]

CLINICAL PRESENTATION

Three phases occur in patients with ATM: initial, plateau, and recovery. The initial phase begins with the presenting symptom and concludes with reaching the neurologic nadir. The plateau phase begins with reaching the neurologic nadir and is a period during which the symptoms are more or less stable. The last phase is recovery, which is the period of slow improvement in neurologic function. The length of time in each phase has been useful for prognostication of recovery and will be discussed later. Patients typically present acutely to subacutely with a combination of sensory and motor deficits. The most common motor symptom is bilateral leg weakness (82%), with a paraplegia developing in 36 percent of cases, although upper extremity weakness is a rare initial feature (4%).[16] Involvement of the arms occurs in 37 percent of patients at some point. Approximately 70 to 90 percent of patients develop bowel and bladder dysfunction, ranging from urinary retention and constipation to incontinence.[14,16] A similar percentage of patients report sensory symptoms, including paresthesias and numbness. Most patients reach their neurologic nadir within 1 week, and patients rarely have worsening of symptoms more than 4 weeks after onset of symptoms.[14,16] Children with extremely rapid evolution of their symptoms (1 to 4 hours) should cause the clinician to take pause and consider a possible ischemic etiology.

The general examination, although usually unremarkable, may reveal signs suggestive of an underlying systemic infection or autoimmune disorder. Fever is not uncommon, with one study reporting its presence in 20 percent of children with ATM.[7] Abdominal examination may reveal a distended bladder. A diffuse or dermatomal vesicular rash or its sequelae suggest concurrent or preceding chickenpox or shingles.

The presence of any mental status changes suggests that the myelitis is a component of a more diffuse process (i.e., acute disseminated encephalomyelitis). In the acute stages, muscle tone is low in affected limbs, but with time may become spastic. Detailed muscle strength testing with objective grading serves as a crucial baseline to compare with serial examinations to determine whether the patient is improving. All sensory modalities should be assessed carefully. In one series, 65 percent of children with ATM had sensory symptoms, with over 80 percent of those children having a clear sensory level.[16] An early case series had suggested that severe pain is a common symptom (88%); however, this is potentially skewed by selection bias of this retrospective study.[14] A spinal cord sensory level usually is located in the thoracic region (58%) and less commonly in the cervical (7%) or lumbar (31%) area.[16] In the acute phase, deep tendon reflexes are depressed in approximately 70 percent of patients and later become hyperactive. Similarly, the Babinski sign

may be negative early in the acute phase but soon becomes positive, indicating upper motor neuron dysfunction.

RADIOLOGIC FEATURES

Every patient with suspected ATM should undergo emergent gadolinium-enhanced magnetic resonance imaging (MRI) of the entire spine to confirm the diagnosis and rule out alternative diagnoses, particularly compressive lesions, such as epidural abscess, epidural hematoma, and extramedullary tumors, which are all potentially neurosurgical emergencies. T1-weighted and T2-weighted sagittal imaging of the entire spine can serve as an initial screen, followed by axial imaging in areas of suspected pathology. In addition, every patient with any neurologic symptoms not referable to the spinal cord should undergo MRI of the brain with gadolinium-enhancement. Optimally, this should include dedicated fine sections through the orbits to evaluate for optic neuritis associated with neuromyelitis optica (NMO). The distinction between idiopathic ATM and NMO is important for both treatment and prognosis. At least one study identified over 40 percent of children diagnosed with ATM with lesions on brain MRI, and the majority of these (65%) did not have symptoms or signs of cerebral involvement, leading the authors to recommend MRI brain scanning in all children with ATM.

Spinal MRI in ATM typically reveals T1-isointense (Fig. 37B-1A) and T2-hyperintense (see Fig. 37B-1B) signals over several contiguous spinal cord segments[14] and may involve the entire spine.[1] The most common finding is a T2-hyperintense lesion involving more than three segments, with one study finding the average length of lesion being more than six segments. The hyperintense signal can extend into the lower brain stem.[1] Spinal cord swelling with effacement of the surrounding cerebrospinal fluid (CSF) spaces may be present in severe cases (see Fig. 37B-1A). Axial imaging typically reveals lesions involving both gray and white matter (Fig. 37B-1D). Contrast enhancement is variably present and may appear diffuse, patchy, or nodular (see Fig. 37B-1C). In some patients with very suggestive clinical features, initial spine MRI may be normal and should be repeated several days later.[14,37,56] In rare cases, the MRI remains normal but does not rule out the diagnosis. A new modality still used exclusively in research that has been applied to ATM is diffusion tensor imaging (DTI). DTI is an MRI sequence that evaluates for the presence and integrity of white matter tracts. One study of a small number of adults with ATM revealed that those individuals with more severe disruption of white matter tracts within the lesion and distal to the lesion had a worse prognosis.[42] In the future, DTI might be useful for stratifying patients for likely prognosis and determining who might benefit from more aggressive treatment.

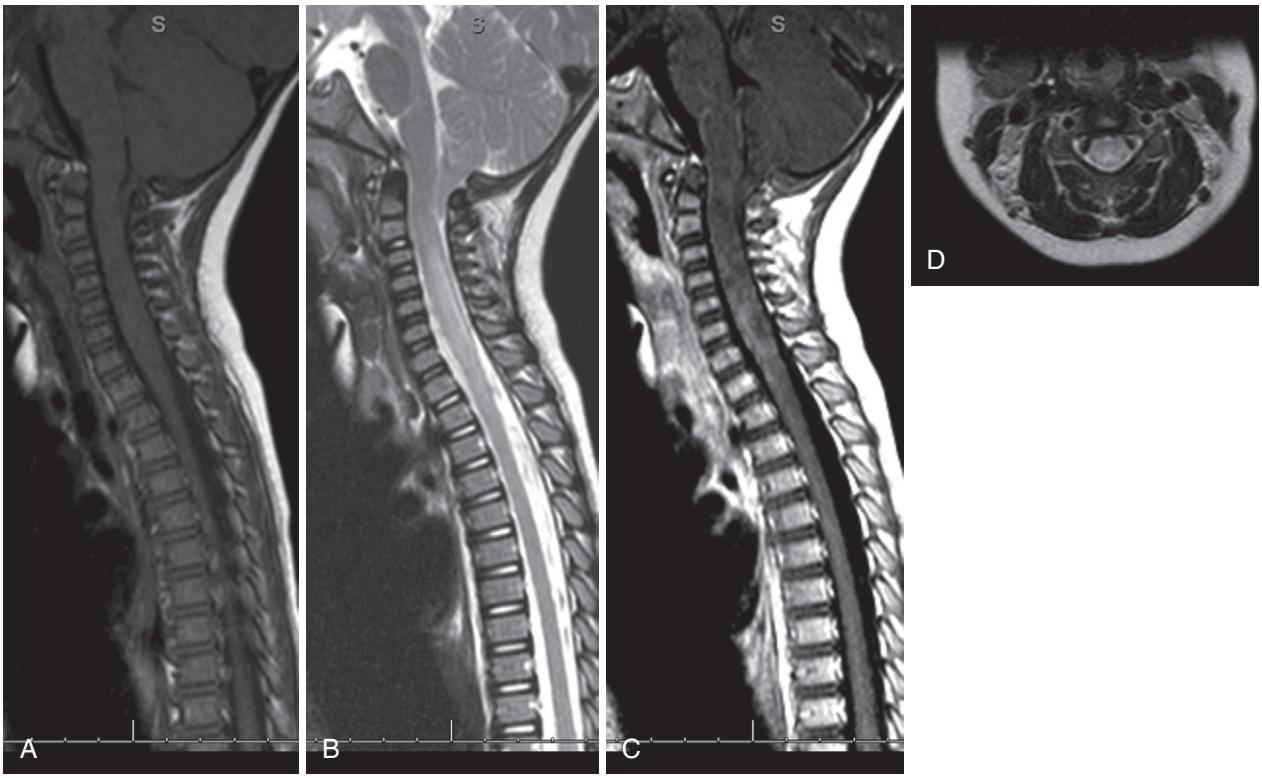

FIGURE 37B-1 ■ Acute transverse myelitis of the cervical cord. **A,** Sagittal T1-weighted magnetic resonance imaging (MRI) sequence through the cervical spinal cord demonstrating swelling of the cord. **B,** T2-weighted MRI sequence of same patient revealing longitudinally extensive hyperintensity through the cervical cord. **C,** T1-weighted MRI sequence with gadolinium revealing patchy enhancement of the cervical cord. **D,** T2-weighted axial MRI sequence through the cervical cord revealing hyperintensity of both gray and white matter.

LUMBAR PUNCTURE

Approximately 50 percent of pediatric patients with ATM have CSF pleocytosis, typically with a lymphocytic predominance.[14,16] Elevated CSF protein levels, either in isolation or in conjunction with pleocytosis, also are detected in approximately 50 percent of patients. Glucose typically is normal. A normal CSF profile does not rule out ATM because this pattern is seen in approximately 25 percent of patients. CSF cytology should be considered for patients with concern for neoplasm. Additional CSF testing is discussed further subsequently.

DIFFERENTIAL DIAGNOSIS

Conditions That Mimic Acute Transverse Myelitis

ATM can be associated with more widespread central nervous system (CNS) demyelinating disorders or systemic autoimmune disorders; in such cases, the term *disease-associated transverse myelitis* has been used. Isolated ATM can be triggered by identifiable preceding infections. Alternatively, ATM can be associated with a nonspecific preceding infection or have no apparent cause; for both of these subgroups, the term *idiopathic ATM* has been used. This last group constitutes the most common category in pediatric ATM. Although the precise pathophysiology of idiopathic ATM is uncertain, the frequent association with preceding infections and vaccinations and accumulating immunologic data suggest an inflammatory cause for the disorder.[11,14,33,55]

Numerous disorders can affect the spinal cord and produce identical symptoms and signs that mimic idiopathic ATM (Table 37B-2). Such conditions must be ruled out through a combination of history, physical examination, neuroimaging, and laboratory evaluation.

Extramedullary Lesions

Extramedullary compressive lesions are neurosurgical emergencies that must be diagnosed rapidly for effective treatment. Spinal epidural abscesses are rare in children. In one series of eight children compiled over a 15-year period at a major children's hospital, seven had fever and all eight had back pain.[5] *Staphylococcus aureus*, some of which were methicillin-resistant, were the most common isolates in this and other series. Other species that have been isolated from spinal epidural abscesses in children include *Salmonella enteritides* (primarily in sickle-cell patients),[5] *Streptococcus pneumoniae*,[8] *Bartonella henselae*,[31] and *Mycobacterium tuberculosis*.[36]

Spinal epidural hematomas also are rare occurrences in children. They can occur spontaneously or may be associated with anticoagulant use, clotting disorders, trauma, or lumbar puncture.[61] Spinal epidural hematomas after lumbar puncture typically self-resolve with no residual sequelae.[38] The first episode of significant bleeding in individuals with hemophilia A has been reported to be a spinal epidural hematoma either forming spontaneously or after lumbar puncture.[29,77] Although they typically cause slowly progressive symptoms (Foix-Alajouainine syndrome), paraspinal arteriovenous malformations can manifest acutely as a result of hemorrhage.[35] Unruptured AVMs usually can be detected as abnormal, dilated vasculature on MRI of the spine; subsequent spinal angiography can confirm the diagnosis.

Spinal cord compression resulting from metastatic disease occurred in about 6 percent of children with solid tumors at some point during their course in one series.[64] The most common responsible tumor types were primitive neuroectodermal tumor, soft tissue sarcoma, and neuroblastoma. When spinal cord compression is the initial manifestation of cancer, as was the case for 67 percent of the patients in this series, it can mimic ATM, although symptoms would in general be expected to more slowly progress than in ATM. Spinal MRI readily distinguishes spinal cord compression from ATM.

TABLE 37B-2 **Conditions That Mimic Idiopathic Acute Transverse Myelitis**

Direct infectious myelopathies
Extramedullary compressive lesions
Epidural abscess
Epidural hematoma
Extramedullary tumors
Guillain-Barré syndrome
Intramedullary spinal cord tumors
Astrocytomas
Ependymomas
Ischemia and infarction
Syringomyelia
Radiation injury
Traumatic spinal cord injury
Vascular malformations

Intramedullary Lesions

Spinal cord infarction is exceedingly rare in children but must be considered in the setting of acute onset of neurologic symptoms referable to the spinal cord. Clinical features and neuroimaging can be used to distinguish ATM from spinal cord infarction, although this can be difficult at initial presentation. Spinal cord infarct typically manifests in a hyperacute fashion (<4 hours from onset to severe neurologic symptoms) with dissociated sensory loss (absent temperature and pain sensation with preserved vibration and proprioception) from thrombosis of the anterior spinal artery.[57] One should inquire about recent trauma, even minor, including to the neck, because this can result in vertebral artery dissection and resultant embolic thrombi to the anterior spinal artery (Fig. 37B-2). Coagulopathies also have been associated with spinal cord ischemia and should be considered.[57] Accompanying MRI signal abnormality in the adjacent vertebral body is highly suggestive of the diagnosis but not universally present at onset of symptoms.[60] Diffusion-weighted MRI also may reveal the presence of ischemia and aid in making the diagnosis; however, diffusion restriction can be difficult to appreciate in the spinal cord.

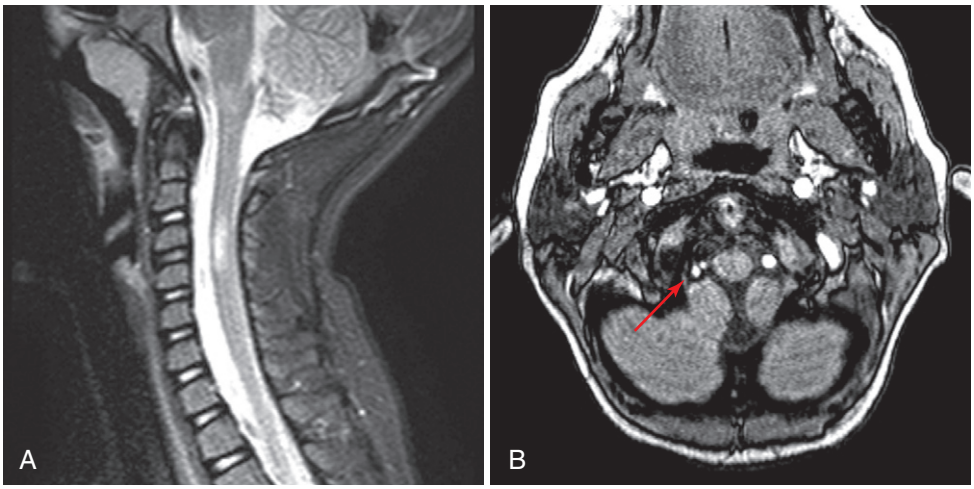

FIGURE 37B-2 ■ Ischemic infarction of the cervical cord. **A,** Sagittal T2-weighted magnetic resonance imaging sequence through the cervical spinal cord revealing hyperintensity of the cord. **B,** Axial magnetic resonance angiogram of the neck revealing a dissection of the vertebral artery on the right of the same patient *(arrow)*. (See companion Expert Consult website for color version.)

The most common intramedullary spinal cord tumors in children are astrocytomas (60%), followed by ependymomas (30%), and finally gangliogliomas (15%).[69] Although biopsy of the tumors is necessary to establish the exact histologic diagnosis, biopsy of the spinal cord rarely is needed to distinguish tumor from ATM. Despite similarities in presenting symptoms, clinical features can help distinguish intramedullary tumors from ATM. Intramedullary spinal cord tumors manifest more subacutely or chronically than does ATM, reflecting their low cellular growth rate.[69] In one study, the mean duration of symptoms before presentation of children with intramedullary spinal cord tumors was 254 days[18] in contrast to ATM, which manifests full symptoms in about 1 week. On examination, the presence of scoliosis or torticollis suggests the presence of longer-standing tumors rather than ATM.[69]

ATM and spinal cord tumors typically are isointense on T1-weighted MRI and hyperintense on T2-weighted images. Although intramedullary tumors display swelling and contrast enhancement more frequently than does ATM, these features also can be seen in the latter. Other radiographic features may be used to distinguish the two entities. The eccentric location of astrocytomas within the spinal cord can be used to differentiate them from ATM, which usually produces symmetric findings.[69] Although ependymomas can produce symmetric spinal cord expansion because of their origin from the central canal, these tumors usually span three to four vertebral segments,[4] whereas pediatric ATM typically involves longer areas of the spinal cord. In addition, an area of low signal intensity reflecting hemosiderin deposits from chronic hemorrhage at the edge of ependymomas also can serve as a radiographic clue.[4] Because patients with intramedullary spinal cord tumors may be diagnosed on the basis of CSF cytologic examination, this test should be considered in all patients with suspected ATM.

The clinical presentation of spinal cord dysfunction in the setting of prior irradiation suggests radiation-induced transverse myelitis as the most likely diagnosis. This entity typically manifests 9 to 18 months after radiotherapy, but it can occur earlier in children.[75]

Syringomyelia typically begins with pain and temperature sensory loss in a capelike distribution over the shoulders. However, if these early symptoms are missed and the syrinx grows, motor disturbances can develop that might be mistaken for ATM. The time course of developing sensory and motor dysfunction in syringomyelia is typically longer than that in ATM. The most common causes of syrinxes in children are tumors and Chiari I malformations.[70] Syringomyelia is readily distinguishable from ATM on MRI.

Peripheral Lesions

The initial clinical presentation of ATM can be quite similar to that of Guillain-Barré syndrome. Both disorders can manifest with back pain, paraparesis, and sensory abnormalities. Although frequently absent in the acute phase, the presence of deep tendon reflexes would strongly indicate ATM. When deep tendon reflexes are absent, the presence of a spinal cord sensory level and bowel and bladder involvement suggests ATM. Some patients with ATM have albuminocytologic dissociation, which is indistinguishable from Guillain-Barré syndrome. In some cases, ATM and Guillain-Barré syndrome can be distinguished only with MRI. Spinal cord, nerve root, and peripheral nerve pathology can coexist in myeloradiculoneuritis, suggesting that ATM and Guillain-Barré syndrome may share a common pathophysiologic mechanism in some cases.[46]

Disease-Associated Acute Transverse Myelitis

Acute transverse myelitis with a presumed inflammatory basis can be associated with recurrent CNS demyelinating disorders and systemic autoimmune disorders. In these cases, the term *disease-associated acute transverse myelitis* can be applied (Table 37B-3).[17]

The presence of encephalopathy and multifocal MRI abnormalities of cerebral white matter points toward acute disseminated encephalomyelitis as a possible diagnosis (Table 37B-4). Spinal cord demyelination in multiple sclerosis tends to be limited to fewer than two vertebral segments with partial cord involvement seen in the transverse plane, resulting in mild, asymmetric symptoms compared with the typically severe, symmetric symptoms in ATM.[67] In addition, the recurrence of lesions over the course of time and in different parts of the CNS is required for establishing the diagnosis of multiple sclerosis.[40] Previous subtle visual or sensory symptoms suggestive of a recurrent demyelinating disorder may be elicited only with detailed questioning. Oligoclonal bands are present more commonly in multiple sclerosis–related myelitis[40] but they also have been reported in idiopathic ATM (Table 37B-5).[57]

ATM is a necessary feature of NMO, a severe, relapsing demyelinating disorder. Specific diagnostic criteria for NMO have been developed and require both ATM and optic neuritis (Table 37B-6).[80] However, ATM may precede optic neuritis by months,[47] and rarely does not occur at all. A novel biomarker (NMO-IgG) targeting the predominant CNS water channel protein aquaporin-4, which is concentrated in astrocytic foot processes in the blood-brain barrier, has been detected in adult patients with NMO.[43,44] Its utility in pediatrics has been confirmed, with one series demonstrating 7/8 children diagnosed with NMO with positive serum NMO-IgG antibodies.[47] In contrast to early criteria that excluded anyone with cerebral MRI findings from a diagnosis of NMO, recent reports have clearly demonstrated that NMO is frequently associated with abnormal brain MRIs and resulting neurologic sequelae to include seizures, intractable hiccups, and aphasia.[47] Because of the potential lag in time from ATM to occurrence of optic neuritis in some children, and the difference in recurrence risk,[78] severity, prognosis, and need for maintenance therapy, every child with ATM should have serum NMO-IgG testing and CSF testing if possible.

ATM also can occur secondary to a variety of systemic autoimmune disorders. Involvement of other organ systems, particularly the skin, lungs, kidneys, and joints, may point to a particular diagnosis, including systemic lupus erythematosus, sarcoidosis, and Sjögren syndrome. A personal or family history of recurrent miscarriages or hypercoagulability is suggestive of antiphospholipid antibody syndrome.

The long list of demyelinating and rheumatologic disorders potentially associated with ATM precludes diagnostic testing for every possible disorder. Table 37B-6 presents a schema to guide which tests should be obtained in patients with ATM.

TABLE 37B-3 Central Nervous System and Systemic Autoimmune Disorders Associated with Acute Transverse Myelitis

Central Nervous System Disorders
Acute disseminated encephalomyelitis
Multiple sclerosis
Neuromyelitis optica
Systemic Autoimmune Disorders
Antiphospholipid antibody syndrome
Behçet disease
Mixed connective tissue disorder
Neurosarcoidosis
Sjögren syndrome
Systemic lupus erythematosus

TABLE 37B-4 Distinguishing Acute Transverse Myelitis from Other Central Nervous System Demyelinating Disorders

Finding	ATM	ADEM	MS	NMO
Myelitis	+	+/–	+/– (partial)	+
Acute mental status changes	–	+	–	–
Optic neuritis	–	+/–	+/–	+

	Varicella-zoster virus[51]	

ROLE OF INFECTIONS IN TRANSVERSE MYELITIS

Infectious Myelopathies

Infectious agents can cause spinal cord dysfunction by directly infecting the spinal cord parenchyma (infectious myelopathy). The etiology of an infectious myelopathy usually is established by positive CSF culture or polymerase chain reaction (PCR) results. Biopsy or autopsy results also have provided evidence of direct CNS infection in some patients. Some authors consider elevated CSF titers without positive culture or PCR results to be sufficient evidence of direct CNS infection, but this issue has not been resolved. In one prospective study, only 3 of 41 cases could be attributed directly to a specific infectious agent (influenza virus A, influenza virus B, and human herpesvirus–6).[16] Viruses constitute the most frequently reported category of infectious myelopathies, with bacteria and parasitic causes being less frequent (Table 37B-7).

Although cases of cytomegalovirus (CMV) myelitis have been reported in immunocompetent adults,[22,74] no cases have been reported in immunocompetent children. Immunocompromised children have been reported to develop CMV myelitis.[28,49] Treatment with ganciclovir or foscarnet should be considered.[9] The combined treatment of CMV-associated myelitis with ganciclovir and methylprednisolone was associated with marked recovery in an immunocompetent adult.[22] As illustrated by CMV, myelitis associated with viral infections may be produced by direct infection, accompanying secondary processes, such as vasculitis, or postinfectious immune-mediated mechanisms. Whether optimal treatment requires antiviral agents or immunomodulation or both is unclear.

Postinfectious Acute Transverse Myelitis

In postinfectious cases, a specific etiology can be suggested by elevated acute or rising convalescent serum titers, isolation of the agent from systemic sources in the setting of a suggestive clinical picture, or both. In such cases, the presumptive pathophysiology entails an aberrant autoimmune response to the spinal cord via mechanisms such as molecular mimicry, rather than direct CNS invasion by the microbe. Over 50 percent of cases of pediatric ATM have been attributed to postinfectious or parainfectious causes.[16] A variety of bacterial and viral pathogens and vaccinations have been associated with postinfectious ATM (Table 37B-8). Within the postinfectious category of ATM, the preceding infection usually is a nonspecific upper respiratory tract infection without an identifiable, specific microbe.[11,14,59] Approximately 50 percent of patients report having had such an infection with an intervening symptom-free interval of 5

TABLE 37B-9 Suggested Diagnostic Workup for Infections Associated with Acute Transverse Myelitis

Blood	Cerebrospinal Fluid	Other
Blood cultures	Bacterial culture	Viral culture of stool and respiratory secretions
Acute and convalescent titers to *Borrelia burgdorferi*	Viral culture	Consider stool ova and parasite testing and serum titers if parasitic infection is suspected
EBV	PCR testing for CMV	
Mycoplasma pneumoniae	EBV	
	Enterovirus	
	HSV	
	M. pneumoniae	
	VZV	

CMV, cytomegalovirus; *EBV,* Epstein-Barr virus; *HSV,* herpes simplex virus; *PCR,* polymerase chain reaction; *VZV,* varicella-zoster virus.

TABLE 37B-10 Additional Diagnostic Workup for Infections Associated with Acute Transverse Myelitis

Blood	Cerebrospinal Fluid	Other
Bartonella titers	Cryptococcal antigen	PPD placement
HIV antibody	HTLV antibody	Stool ova and parasite testing
HTLV-1 antibody	Fungal culture	
Parasitic infection titers	VDRL	
RPR		

HIV, Human immunodeficiency virus; *HTLV,* human T-cell lymphotrophic virus; *PPD,* purified protein derivative; *RPR,* rapid plasma reagin; *VDRL,* Venereal Disease Research Laboratory.

to 10 days.[11,14,59] In instances in which the specific microbe is not identified and in cases in which no associated infection, systemic disorder, or recurrent demyelinating disorder is identified, the term *idiopathic acute transverse myelitis* has been applied.

The long list of potential pathogens precludes performing diagnostic testing for every possible agent. The workup instead should focus on the pathogens that are common, treatable, or suggested by particular clues in the history or examination. Table 37B-9 lists the infectious disease tests that should be performed in every patient with ATM. Additional infectious disease tests that should be considered, depending on the clinical scenario and immune status, are listed in Table 37B-10.

ROLE OF THE IMMUNE SYSTEM IN IDIOPATHIC ACUTE TRANSVERSE MYELITIS

Several lines of evidence have implicated derangements in the immune system as the primary mechanism of damage in idiopathic ATM. First, neuropathologic studies have identified inflammatory cell invasion within the spinal cord parenchyma.[6] Both antibody-mediated damage and cell-mediated damage have been implicated, similar to findings in multiple sclerosis. Second, the production of interleukin (IL)-6 by astrocytes seems to lead to nitric oxide–induced injury to spinal cord oligodendrocytes and axons in patients with idiopathic ATM. IL-6 levels are markedly elevated in the CSF of patients with ATM and correlate with long-term disability.[33] Third, immunosuppressive therapies, including intravenous methylprednisolone, plasma exchange, and cyclophosphamide, have been used successfully as treatment for idiopathic ATM.

TREATMENT

All patients with ATM should be hospitalized for further monitoring and treatment. Most patients can receive care on the regular ward, although the approximately 5 percent of patients with respiratory involvement from cervical myelitis require intensive care monitoring and may need endotracheal tube placement and mechanical ventilation.

No randomized, controlled treatment trials in ATM in children have been done. Based on case reports and series that have suggested a beneficial effect,[15,41,68] high-dose corticosteroids have become the standard of care in ATM. In one series of 12 children with severe ATM compared with a historical control group of 17 patients, the use of high-dose intravenous methylprednisolone significantly increased the proportion of children walking independently at 1 month (66% vs. 18%) and with full recovery at 1 year (55% vs. 12%).[15] Although a variety of agents and courses have been used, we use intravenous methylprednisolone 30 mg/kg per dose for 5 days, with a maximum of 1 g per day. The need for a prednisone taper is controversial; however, we use a slow taper over 3 to 4 weeks beginning with 1 mg/kg/day. Most patients improve, often dramatically, with intravenous steroid treatment. Although some patients may improve spontaneously,[59] the collective data suggest that high-dose intravenous methylprednisolone should be used in all patients with ATM. The use of adjunctive immunomodulating therapies has been demonstrated to be beneficial in a subset of adults with ATM—those with complete motor and sensory loss below the level of the spinal cord lesion. The adjunctive therapies include plasma exchange and cyclophosphamide. Furthermore, a recent evidence-based guideline from the American Academy of Neurology cites class II evidence that plasmapheresis should be used in addition to intravenous methylprednisolone for fulminant demyelination. In our experience, any child with complete motor and sensory loss or without improvement with 1 or 2 doses of intravenous methylprednisolone should begin every other day plasma exchange with complete plasma volume exchange with each treatment for six sessions. Children who continue to have severe impairment with minimal improvement after both high-dose intravenous methylprednisolone and plasma

exchange warrant consideration of immune depletion with cyclophosphamide.

The use of antimicrobial agents in patients with ATM is controversial. Because most cases are caused by secondary, immune-mediated mechanisms, such treatment may not have significant benefit. Antimicrobial therapy is indicated, however, in cases with highly suspected or proven direct or associated infections, such as doxycycline for *Mycoplasma*,[73] ganciclovir for CMV,[22] and acyclovir for herpes simplex virus and varicella-zoster virus.[24] When antimicrobials are used, agents with good CSF penetration are preferred because direct invasion of the CNS may be present in some cases.

Additional treatment includes neuropathic pain management with gabapentin or pregabalin, urinary bladder catheterization, bowel regimens, and peptic ulcer and deep venous thrombosis prophylaxis. The early institution of clean intermittent catheterization may improve long-term neurourologic outcomes in children with ATM.[71] Physical therapy should be instituted early to maximize the chance for recovery and continued in inpatient rehabilitation or an outpatient setting after the patient has been discharged from the acute care hospital.

OUTCOME AND PROGNOSIS

Recurrences

In contrast to adult patients with idiopathic ATM, who have an approximately 25 percent likelihood of experiencing relapses,[17] most pediatric patients with idiopathic ATM do not have any recurrences. Three series have evaluated the recurrence risk for further episodes of demyelination after an episode of ATM.[54,76] A total of 82 pediatric patients were followed, with 4 developing a second demyelinating event. Of these, 2 were ultimately diagnosed with multiple sclerosis and another 2 eventually met criteria for NMO. This suggests that in contrast to adults with ATM, the risk for a more widespread demyelinating disorder is low after an initial event of ATM. However in our experience, rarely ATM can recur in children.

Disability

During recovery, motor function typically returns first, with an average time to independent ambulation of 56 days in one study[14] and 25 days in a group of patients treated with high-dose intravenous methylprednisolone.[15] Bowel and bladder control recover more slowly, with an average time to recovery of normal urinary function of 7 months.[14] Another study confirmed worse prognosis for sphincter control with more than half of children with ATM having modified or complete sphincter dependence at, on average, 8 years of follow-up.[63] Mobility and locomotion were also at least partially impaired in 36 and 33 percent, respectively, at follow-up, although full recovery is possible.[19]

Multiple studies have evaluated prognostic factors in children with ATM. Unfavorable outcomes have been linked with early age of onset, complete paraplegia, rapid evolution to neurologic nadir, absence or diminished deep tendon reflexes, and high rostral border of sensory level. Favorable outcomes were associated with a plateau phase of 8 days or less, normal white blood cell count in CSF, diagnosis within seven days of symptom onset, few segments of spinal cord involved, and treatment with high-dose methylprednisolone.[14,56,63] Levels of the intracellular neuronal 14-3-3 protein in the CSF of patients with ATM may reflect the extent of neuronal injury and correlate with outcome.[32,33]

SECTION V

GENITOURINARY TRACT INFECTIONS

CHAPTER 38

URETHRITIS

Ellen R. Wald

Urethritis is an inflammation of the urethra and periurethral tissues in males and females. It may be associated with a variety of infectious and noninfectious disorders.

EPIDEMIOLOGY

The cause of urethritis varies with the age of the patient, sexual practices, and hygienic standards.[9,39] *Chlamydia* infections and gonorrhea are common occurrences in adolescents; fecal contamination or irritation caused by physical or chemical substances is a more usual occurrence in preschool-aged children. Transmission during sexual activity is the usual means of spread of *Neisseria gonorrhoeae* and *Chlamydia trachomatis* in teenagers and in sexually abused patients; nonvenereal transmission has been described in prepubertal children.[16] Manifestations after nonvenereal spread has occurred may include urethritis, vaginitis, balanitis, conjunctivitis, and complications of disseminated infection (arthritis, meningitis).[11,16]

The home and social environments of prepubertal children must be examined to identify fully the pattern of spread and infection in the patient and contacts because complex psychosocial diagnoses and therapies often are involved.[33] Children with gonorrhea and chlamydial infections are concentrated in large urban centers, usually in poor socioeconomic environments.

Although nonvenereal transmission of *N. gonorrhoeae* is well-established, gonococcal infections in children 2 to 10 years of age should be considered evidence of probable sexual abuse.[1,17,19-21] Household contacts have been found to have positive cultures in 27 to 63 percent of such cases. Prepubertal girls infected with *N. gonorrhoeae* as a result of sexual abuse outnumber boys by a ratio of at least 3 : 1 and in one report 8 : 1.[13]

PATHOPHYSIOLOGY

Infection caused by *N. gonorrhoeae* usually is localized to the urethra in boys and to the vagina in girls; however, rectal and pharyngeal carriage sometimes occurs in the absence of urethral colonization. Gonococcal virulence factors include pili, the ability to attach to urethral epithelial cells, and production of extracellular proteases that cleave IgA. Initial attachment of gonococci to the surface of columnar epithelial cells is mediated by pili, which are filamentous outer membrane appendages composed of multiple subunits, the most important of which is pilin.[38] Local invasion involves multiple adhesins interacting with host receptors at the mucosal cell level. After attachment occurs, gonococci become engulfed in a process known as parasite-directed endocytosis.[14] The organisms are able to undergo intracellular replication within phagocytic vacuoles and columnar epithelial cells, which is a successful adaptive response promoting survival.

Chlamydia infections are the most frequent cause of sexually transmitted infection in the United States.[5,7,44] Chlamydiae are structurally complex organisms that are obligate intracellular parasites and contain DNA and RNA. Attachment, which is not understood completely, is the first step in the infectious process of the susceptible host cell. It is followed by phagocytosis and then the failure of cellular lysosomes to fuse with the phagosome containing the elementary body, which may be mediated partly by macromolecules in the chlamydial cell envelope. After these two crucial events occur, the elementary bodies undergo biologic changes, and after approximately 72 hours, they are released from the host cell as new infective elementary bodies (Fig. 38-1).

Urethritis in younger children also may be caused by the introduction of fecal bacteria or pinworms into the urethra during the early years of toilet training, particularly in girls. Inflammation may be related to bubble baths and other chemical and physical irritants. The entity of idiopathic urethritis is also observed in young boys and girls as a cause of dysuria and hematuria.[24] Edema of the mucosa and the presence of inflammation and red blood cells are common histopathologic features of urethritis that lead to dysuria, hematuria, and microscopic pyuria.

CLINICAL PRESENTATION

Gonococcal urethritis is characterized by a 2- to 7-day incubation period after sexual intercourse. The onset often is sudden, with dysuria and copious urethral discharge in boys and leukorrhea in girls. The urethral discharge often is thick, profuse, and yellow. The patient usually has no fever. In prepubertal girls, leukorrhea is more prominent as a sign of gonococcal infection (reflecting a vulvovaginitis) and urethritis occurs less commonly. This difference may be related to the method of infection and the different sensitivity of the vaginal epithelial surface to infection in a prepubertal child. Leukorrhea may be minimal in adolescent girls, and dysuria may be absent.[1]

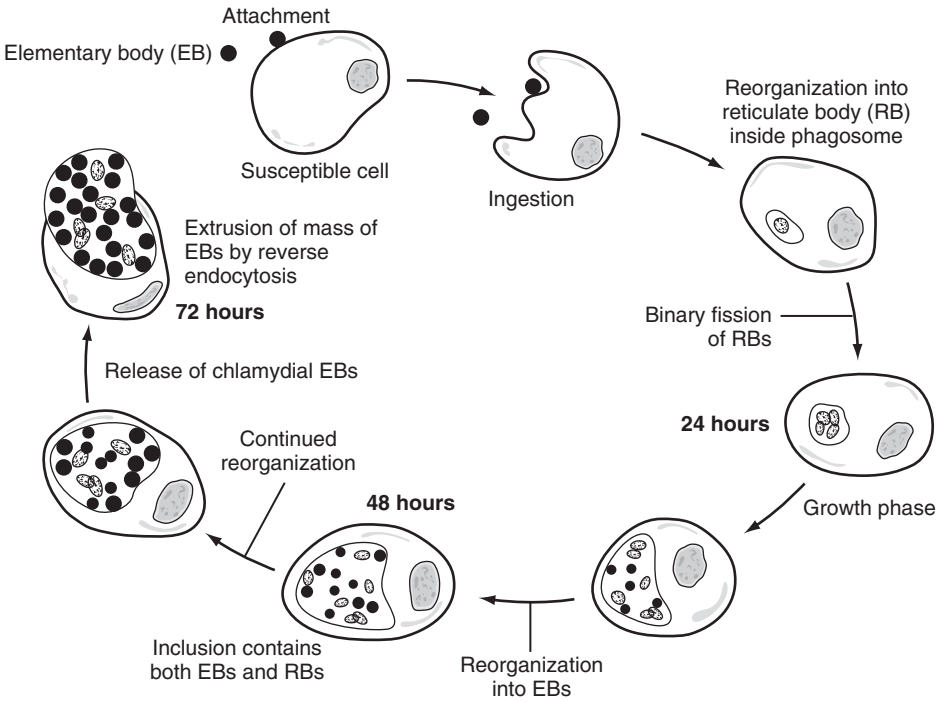

FIGURE 38-1 ■ Schematic description of the growth cycle of *Chlamydia trachomatis*. (From Batteiger BE, Jones RB. Chlamydial infections. *Infect Dis Clin North Am* 1987;1:55–81.)

Diagnosis often is made earlier in adolescent boys than in girls, perhaps because of the prominence of urethral discharge in boys and misinterpretation of the significance of leukorrhea in girls. Gonococcal urethritis also may cause asymptomatic pyuria in boys. Occasionally, prepubertal patients have conjunctivitis or balanitis without significant urethritis. Clinical presentations include systemic illness with fever, arthritis, and skin lesions secondary to bacteremia in 3 percent of untreated individuals with mucosal gonorrhea.[1] These lesions often begin on the extremities as small erythematous macules that progress to circular papules with an area of central necrosis.

The clinical presentation of nongonococcal urethritis may be similar to that described for gonorrhea, but it more commonly has a longer incubation period (often 8 to 14 days after sexual intercourse) and a scanty exudate, which may be clear and intermittent. This condition also is referred to as *nonspecific urethritis* and may be present in association with or subsequent to gonococcal urethritis. In the latter case, the scant urethral discharge may persist after the patient has been treated for gonorrhea. Asymptomatic urethral colonization with *C. trachomatis* also is reported in males.[15,42]

An equivalent syndrome, acute urethral syndrome, has been described in sexually active females. The patient experiences an acute onset of dysuria and increased frequency, and pyuria (≥10 white blood cells/mm^3 of midstream urine) is a common finding. Bacterial cultures of the urine often are sterile or show less than 10^5 bacteria/mL; coliform bacteria, *Staphylococcus saprophyticus*, and *C. trachomatis* are the most common causes. Clinical expression of infection with *C. trachomatis* in adolescent girls is characterized by a yellowish, mucopurulent secretion at the cervical os.[6] However, infection with *C. trachomatis* may be asymptomatic in both sexes, an important consideration in designing effective strategies for diagnosis and management of sexual contacts.

A patient with urethritis caused by trauma may have hematuria and dysuria without fever. The trauma may be obvious or related to masturbation or introduction of foreign bodies into the urethra. Patients with urethritis secondary to bubble bath or detergent usually have transient dysuria and no systemic signs. Fecal contamination of the urethra may be accompanied by hematuria, dysuria, and pyuria.

DIFFERENTIAL DIAGNOSIS

Table 38-1 lists the differential diagnoses for urethritis.

Noninfectious

Trauma, bubble bath, detergents found in shampoos, masturbation, radiation, dysfunctional elimination syndrome, and caustic substances may lead to the development of urethritis.[24] Idiopathic urethritis of childhood is characterized by blood spotting of underwear between voids or microhematuria with or without dysuria and urethral discharge.[24] Urethritis also may be a component of several systemic syndromes, including erythema multiforme (Stevens-Johnson syndrome), Kawasaki disease, and occasionally other forms of allergy. Reiter syndrome denotes the association of nongonococcal urethritis with conjunctivitis and arthritis.

Infectious

The most common forms of urethritis in sexually active adolescents and young adults are gonococcal and so-called nongonococcal urethritis. They may occur together or sequentially. Nongonococcal urethritis has been related causally to infections with *C. trachomatis* in approximately 15 to 40 percent of cases. *Mycoplasma genitalium* is associated with signs and symptoms of urethritis in 15 to 25 percent of nongonococcal urethritis in the United States.[29,37] The role, if any, of *Ureaplasma urealyticum* is currently unclear. The remaining cases of infectious urethritis in postpubescent, sexually active patients may be caused by a variety of pathogenic microorganisms, including *Gardnerella vaginalis*, *Mycoplasma hominis*, *Trichomonas vaginalis*, *Candida albicans*, herpes simplex virus type 2, *Treponema pallidum* (syphilis), and other bacteria, such as staphylococci, Enterobacteriaceae, and occasionally streptococci, including group B.[15] Studies also have implicated a causative role in *Chlamydia*-negative nongonococcal urethritis for anaerobic organisms of the *Bacteroides* spp., in particular *Bacteroides urealyticus*.

In younger children, urethritis usually has noninfectious causes as outlined earlier. Gonorrhea, *Chlamydia*, and fecal bacteria may be important as well.

TABLE 38-1 **Etiology of Urethritis**

Infectious	Noninfectious
Sexually Transmitted Infections	**Vasculitides**
Neisseria gonorrhoeae	Reiter syndrome
Chlamydia trachomatis	Erythema multiforme
Trichomonas vaginalis	Kawasaki disease
Herpes simplex virus type 2	
Mycoplasma spp.	**Mechanical**
	Masturbation
Non-Sexually Transmitted Infections	Foreign body
	Trauma
Staphylococcus saprophyticus	
Enterobacteriaceae	**Dysfunctional Elimination Chemical**
Gardnerella vaginalis	
Streptococcus spp.	Soaps
Enterobius vermicularis	Detergents
	Drugs

SPECIFIC DIAGNOSIS

A standard method for diagnosing gonorrhea in a sexually active male is to obtain urethral discharge by manually stripping the urethra or, if that is unproductive, by gently inserting a swab 2 to 3 cm into the distal urethra. The best culture technique for isolating *N. gonorrhoeae*, a fastidious organism, is immediate inoculation of this material onto a selective growth medium, such as regular or modified Thayer-Martin agar. Any delay in inoculation of the plates necessitates the use of a transport method with growth media in a carbon dioxide environment that support the gonococcus at ambient temperatures. These media protect the organism from its marked susceptibility to the effects of drying, cold, and overgrowth by other bacteria. Urethral exudate from a male patient should be gram-stained at the same time; typical kidney bean–shaped, gram-negative, intracellular diplococci are presumptively diagnostic, with a sensitivity and specificity approaching 100 percent (Fig. 38-2).

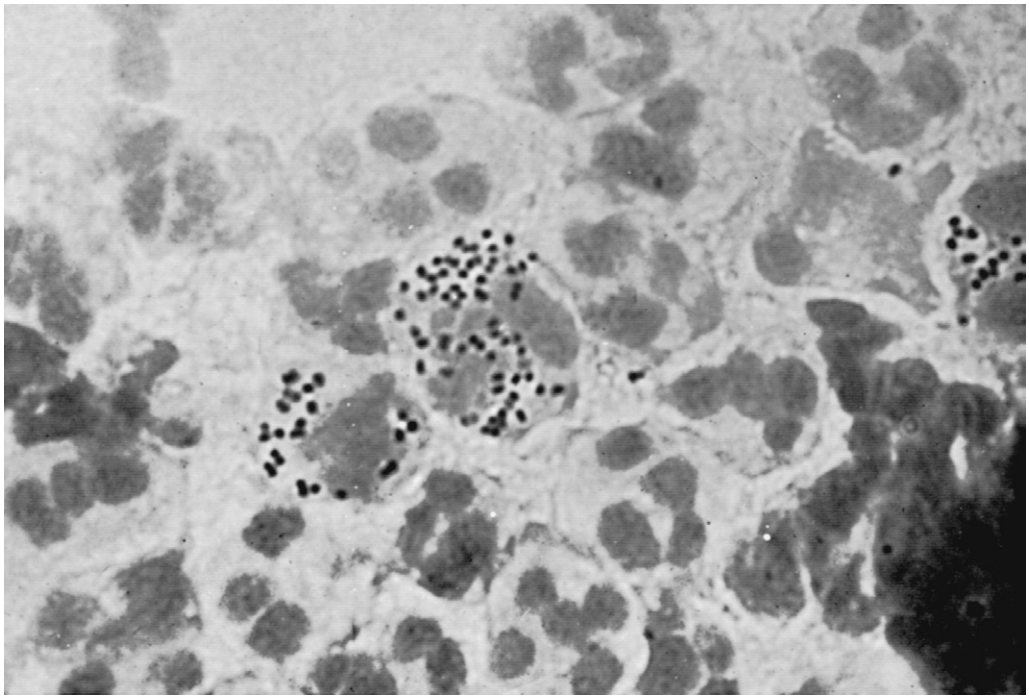

FIGURE 38-2 ■ Gram-stained smear of urethral discharge from a teenage boy with gonorrhea.

Putative gonococcal colonies should be confirmed by oxidase reaction, Gram staining, sugar use tests, rapid enzyme tests, nucleic acid probes, or agglutination reactions with antibodies specific for *N. gonorrhoeae*. The last four tests are especially important in evaluating sites of infection (e.g., the pharynx) or populations of patients with a low prevalence of gonorrhea.

Sexually active females with urethritis also should undergo urethral culture. Although the Gram stain of cervical secretions is only 66 percent sensitive in detecting *N. gonorrhoeae* in adolescent girls, the finding of kidney bean–shaped, intracellular gram-negative diplococci is highly specific and helpful.[45] Vaginal, cervical, and rectal swabs are recommended. Asymptomatic colonization with gonococci seems to occur most commonly in female patients, although it has been described in adolescent boys.[1,23] Pharyngitis, conjunctivitis, balanitis, and other, less common, manifestations of gonorrhea may coexist with urethritis. Samples obtained from these sites should be handled as described earlier. Blood agar and other specialized media may be indicated to identify nongonococcal causes of urethritis.

Nucleic acid amplification tests are highly sensitive and specific when used on urethral swab (males), endocervical swab, patient-obtained vaginal swabs, and urine specimens.[7] These tests include polymerase chain reaction (PCR), transcription-mediated amplification, and strand displacement assays. Only the transcription-mediated assay is approved by the U.S. Food and Drug Administration (FDA) for testing vaginal swabs from postmenarcheal females.[1] Use of urine specimens increases the feasibility of initial testing and follow-up of hard-to-access populations such as adolescents.[1] These techniques also permit dual testing of urine for *C. trachomatis* and *N. gonorrhoeae*. Nucleic acid amplification tests are not recommended for rectal and pharyngeal swabs.[1] However, some noncommercial laboratories have initiated nucleic amplification testing of rectal and pharyngeal swab specimens after establishing the performance of the test to meet requirements of the Clinical Laboratory Improvement Amendments (CLIA). Although none of these tests is superior to culture, their ease of use (i.e., for urine or self-obtained specimens) renders them extremely attractive.

Gonococcal urethritis in prepubescent boys is diagnosed as described earlier for adolescent boys. Vaginal swabs are most useful in female patients, although vaginal discharge may not be prominent. Endocervical cultures are not recommended for the diagnosis of gonorrhea in prepubescent girls. The yield of vaginal swabs seems to be adequate for most diagnostic purposes; rectal swabs also may be useful in female patients. Showing kidney bean–shaped, gram-negative intracellular diplococci in a prepubescent boy and girl is useful for establishing a presumptive diagnosis and instituting therapy. Confirmation by culture as described for a sexually active male is necessary.

Other infectious causes of urethritis may be diagnosed by specific techniques, including wet mount or nucleic acid amplification for *Trichomonas*, Gram stain, and culture on Sabouraud dextrose agar for *C. albicans*, and culture or PCR for herpes simplex virus, used in the patients and their contacts. New culture techniques for *Chlamydia*, such as the use of microtiter cell monolayers, have increased the recovery rates, decreased the cost, and shortened the turnaround time for the isolation of *C. trachomatis*.[2] The rigorous transport conditions and the small number of laboratories with cell culture techniques have limited the availability of *Chlamydia* cultures; however, nonculture methods, including direct immunofluorescence staining of smears with use of monoclonal antibodies,[2,18,25,28,40] enzyme-linked immunosorbent assay (ELISA) techniques, and nucleic acid amplification testing, are available.

The use of immunofluorescence and ELISA techniques has been surpassed in sensitivity and ease of use by nucleic acid amplification testing. Nucleic acid amplification tests such as PCR, transcription-mediated amplification, and strand displacement assays are available and are more sensitive than cell culture, DNA probe, direct fluorescent antibody tests, or ELISA, although specificity varies in contrast to culture.[1] PCR, strand displacement assay, and transcription-mediated amplification are useful for evaluating urine specimens from either sex. The FDA has approved transcription-mediated amplification for testing vaginal swabs from postmenarcheal adolescents. Nucleic acid amplification tests are not yet recommended for specimens obtained from rectal or pharyngeal swabs or for urethral swabs from females.

When documentation of infection is being sought in cases of suspected child abuse, performing cultures is strongly preferred and may be the only acceptable test in certain jurisdictions.[1] When culture is unavailable, some experts support using nucleic acid amplification testing if a positive result can be verified by another nucleic acid amplification test. ELISA and fluorescent antibody tests should not be used for testing rectal, vaginal, or urethral specimens from infants and children because of low sensitivity and specificity.[1] A recent multicenter investigation showed nucleic acid amplification tests for detection of *C. trachomatis* and *N. gonorrhoeae* in children being evaluated for child abuse were superior to culture.[4]

Ureaplasma and other genital *Mycoplasma* spp. currently can be identified only by culture. This test should be reserved for the evaluation of recurrent cases of urethritis with poor response to treatment.[25] Specimens of urethral and vaginal discharge secondary to fecal contamination and foreign bodies can be examined by conventional diagnostic bacterial techniques.

TREATMENT

Table 38-2 presents antibiotic regimens for treatment of urethritis. The treatment of urethritis should include treatment of the sexual partners of the index case to avoid reinfection and further spread of infection. Patients with urethritis frequently have mixed infections with *N. gonorrhoeae* and the pathogens linked with nongonococcal urethritis, such as *C. trachomatis*. Concurrent infection with *N. gonorrhoeae* and *C. trachomatis* is documented frequently. In a survey of adolescents admitted to juvenile detention centers throughout the United States, screening for sexually transmitted infections was performed on

TABLE 38-2 **Antibiotic Regimen for Urethritis**

Nongonococcal Urethritis	
Recommended regimen	Azithromycin 1 g orally in a single dose *or* Doxycycline 100 mg orally twice daily for 7 days
Alternative regimen	Erythromycin base 500 mg four times daily for 7 days *or* Erythromycin ethylsuccinate 800 mg four times daily for 7 days *or* Ofloxacin 300 mg twice daily for 7 days *or* Levofloxacin 500 mg once daily for 7 days
Chlamydial Infection	
Recommended regimen (adults and adolescents)	Azithromycin 1 g orally in a single dose *or* Doxycycline 100 mg orally twice daily for 7 days
Alternative regimens	Erythromycin base 500 mg four times daily for 7 days *or* Erythromycin ethylsuccinate 800 mg four times daily for 7 days Ofloxacin 300 mg twice daily for 7 days *or* Levofloxacin 500 mg once daily for 7 days
Children	
<45 kg	Erythromycin 50 mg/kg/day in 4 divided doses for 14 days
≥45 kg and <8 years old	Azithromycin 1 g orally in a single dose
>8 years old	Use same regimen as for adults
Gonococcal Infection	
Recommended regimen (adults and adolescents)	Ceftriaxone 125 mg IM in a single dose *or* Cefixime 400 mg orally in a single dose *plus* Regimen effective for *Chlamydia*
Children	
<45 kg	Ceftriaxone 125 mg IM in a single dose Cefixime 8 mg/kg (maximum 400 mg) orally in a single dose
If bacteremia, arthritis, or meningitis	Ceftriaxone 50-100 mg/kg/day (maximum 2 g/day) IV for 7-14 days
≥45 kg	Use adult regimen

IM, Intramuscularly; *IV,* intravenously.

adolescent girls with gonorrhea. Fifty-four percent were coinfected with chlamydia; of adolescent boys infected with gonorrhea, 51 percent were coinfected with *Chlamydia*.[26] A study determining chlamydia and gonorrhea co-occurrence in a high school population showed similar results: of 117 students with gonorrhea, 50 (42.7%) had chlamydia; of 451 with chlamydia, 50 (11.1%) had gonorrhea.[34] Patients with gonococcal urethritis also are at risk for development of early-incubating syphilis. One must consider these factors and the possibility of systemic infection when choosing a treatment regimen for urethritis.[31]

Sexual abuse is the most common cause of gonococcal infection among children 2 to 10 years of age. Anorectal and pharyngeal infections with *N. gonorrhoeae* are common and frequently asymptomatic occurrences among these patients.[32]

In 2010, the Centers for Disease Control and Prevention (CDC) published treatment guidelines for sexually transmitted diseases, including urethritis (see Table 38-2). Every attempt should be made to ascertain the specific diagnosis. If doing so is impossible, the treatment regimen chosen always should be appropriate for nongonococcal urethritis and gonococcal infection. The emergence of penicillin-resistant and tetracycline-resistant strains of *N. gonorrhoeae* has led to the abandonment of penicillin and tetracycline for the treatment of gonorrhea.[12]

Single-dose azithromycin for nongonococcal urethritis and either intramuscular or oral single-dose regimens for uncomplicated gonococcal infections are likely to increase compliance.* Unfortunately, rare reports of isolates of *N. gonorrhoeae* resistant to cefixime and ceftriaxone have been noted in Japan and France.[43] Test of cure is not indicated for uncomplicated gonococcal or chlamydial infection when single-dose treatment regimens are used.[7] Emergence of resistance to quinolones initially restricted the use of these drugs in cases of gonorrhea that originated from California, Hawaii, and Asia,[1,3,7] However, in 2007, the CDC recommended that fluoroquinolones no longer be used for treatment of gonorrhea.[8] If these regimens fail, infections with other pathogens, such as herpes simplex virus, *T. vaginalis*, or bacterial urethritis should be considered. Appropriate testing and specific treatment should be provided when indicated.

PROGNOSIS

Gonococcal urethritis may subside and lead to asymptomatic carriage in female patients. Carriage may last for weeks to months in adults; this period is undefined in children. Untreated gonococcal urethritis also may lead to prostatitis and epididymitis in male patients and urethral stricture. Asymptomatic genital infections in women can progress to pelvic inflammatory disease with tubal scarring and infertility. Systemic complications of asymptomatic gonorrheal infections include arthritis, endocarditis, and necrotic skin lesions.

Chlamydial infections frequently have been associated with pelvic inflammatory disease in women, sometimes

*References 21, 22, 27, 30, 35, 36, 41, 46.

resulting in infertility or ectopic pregnancy. *Chlamydia* can be transmitted to a newborn in the birth canal, which can result in conjunctivitis, pneumonia, or both. Prenatal screening for *C. trachomatis* has limited this problem in the United States.

PREVENTION

Despite substantial efforts, a specific gonococcal vaccine has not been developed. The mainstays of prevention continue to be education and screening. Prepubescent gonorrhea can be prevented from recurring only by careful family counseling and psychosocial therapy; legal intervention may be necessary.

The availability of diagnostic tests performed on urine (a noninvasive alternative to specimens obtained from the urethra or endocervix) renders extensive screening possible in nontraditional settings such as schools and recreation centers.[20] Large-scale efforts that have implemented screening for all sexually active teens attending school-based clinics have been successful in reducing the prevalence of *Chlamydia* infection in boys.[10]

Prevention of noninfectious causes of urethritis usually depends on education and specific counseling of the family. Physical agents or allergens identified as a cause of urethritis must be removed.

CHAPTER 39

Cystitis and Pyelonephritis

Ellen R. Wald

Urinary tract infections (UTIs) are the most common serious bacterial infections in children.[124] In several series of children evaluated for fever, UTIs accounted for 5 to 6 percent of infections. They are more common than occult bacteremia, bacterial pneumonia, and bacterial meningitis. UTIs are especially common as causes of infection in white female infants, and they may explain febrile episodes in nearly 20 percent of such infants.

EPIDEMIOLOGY

UTIs occur in all age groups and may be symptomatic or asymptomatic. Factors that affect the incidence of UTIs are associated with gender, age, race, circumcision status, and general health.[96] The site of infection may be the bladder (cystitis), ureters (ureteritis), pelvis (pyelitis), and renal parenchyma (pyelonephritis). Infections in neonates and infants are common occurrences. In the first 3 months of life, infections in uncircumcised male infants are most common.[126,137] Beyond 6 months, infections in female infants are substantially more common than are infections in male infants; the female predominance of UTIs is maintained throughout the remainder of childhood and adolescence.[30]

Risk for Urinary Tract Infection

The risk for developing a UTI during childhood seems to have increased since early studies by Winberg and colleagues[172] in 1960. These investigations showed that the risk for developing a UTI during the first 10 years of

life was 3 percent in girls and 1.1 percent in boys. In a more recent retrospective study of a cohort of 3556 school entrants, 7.8 percent of girls and 1.6 percent of boys were found to have had symptomatic UTIs as confirmed by significant bacteriuria.[48] In approximately half of these cases, the clinical presentation was consistent with acute pyelonephritis (APN).[43] Another population-based study was performed in Göteborg, Sweden, to describe the incidence of first-time symptomatic UTI in children younger than 6 years old. The prevalence during the first 6 years of life was 6.6 percent for girls and 1.8 percent for boys.[97] The apparent increase in risk most likely relates to an increased awareness of the diagnosis of UTI as an explanation for fever in children and the more frequent practice of culturing the urine of children who are ill.

Several studies have investigated systematically the prevalence of UTI as the explanation for fever in febrile young children presenting to the emergency department. Although the definition of significant bacteriuria has varied among studies, the overall prevalence of UTI is 3.3 to 5.3 percent.[51,144] White female infants had significantly more UTIs than did black male infants. Higher prevalences occurred in uncircumcised male infants or male infants with abdominal or suprapubic tenderness on examination.[144] White female infants with a temperature of 39°C (102.2°F) or greater had a prevalence of UTIs of 17 percent.[58] In a large prospective study of febrile (temperature ≥38°C [100.4°F]) infants 3 months or younger evaluated in pediatric office settings, 54 percent of infants had urine tested and 10 percent had UTIs.[106]

A recent meta-analysis searched all publications on UTI in children from 1966 to 2005.[141] The overall prevalence of UTI was found to be 7 percent, but it varied greatly depending on age, gender, and circumcision status.[125] The prevalence was higher in white infants (8%) than black infants (4.7%) and was highest in uncircumcised male infants younger than 3 months of age and in female infants younger than 12 months of age.

Risk Factors for Urinary Tract Infection

Uncircumcised Boys

The common problem of UTIs in uncircumcised boys, although suspected in the 1970s, was first documented in the 1980s by Ginsburg and McCracken.[34] The strongest evidence of a causal link between an intact foreskin and a UTI comes from several studies conducted by Wiswell and colleagues.[175] In their series, an overall 10-fold increased incidence of UTI was found in uncircumcised compared with circumcised male infants (1.12% vs. 0.11%; $p < .001$).[175] Wiswell and other investigators have continued to document this problem.[137,145,174] In the recent meta-analysis by Shaikh and associates, among febrile male infants younger than 3 months of age, 2.4 percent (confidence interval [CI], 1.4 to 3.5) of circumcised males and 20.1 percent (CI, 16.8 to 23.4) of uncircumcised males had a UTI.[141] Where and when rates of circumcision have decreased, the frequency of UTIs in boys has increased. The presence of preputial folds in uncircumcised boys encourages a high density of bacterial growth and contamination of the urethral opening.[15] Circumcision reduces meatal contamination, decreasing the ascent of bacteria into the bladder.[174] The high risk for acquiring UTIs in uncircumcised boys diminishes with age (as the foreskin becomes more retractable) but is still present in the toddler age group.[22]

Dysfunctional Voiding

Dysfunctional voiding is a risk factor for the development of a UTI and an occasional consequence of UTI. Dysfunctional voiding refers to a lack of coordination between the two functions that are essential for normal voiding to occur—relaxation of the urethral sphincter and contraction of the detrusor muscle of the bladder. Ordinarily, the sphincter must relax as the detrusor contracts.[5] The failure of the sphincter to relax causes an obstruction to the outflow of urine. Consequently, voiding pressures and intravesicular pressure are high, the bladder becomes overdistended, dribbling instead of a good flow occurs, and residual urine remains in the bladder after the void. This dyscoordination is termed *dyssynergia*.[5]

Clinical manifestations typically appear after toilet training and include incontinence, enuresis, urinary urgency, and UTI.[28] Constipation is a common occurrence because of the inability to relax the musculature of the pelvic floor. The presence of dysfunctional voiding also may promote the persistence of vesicoureteral reflux (VUR) and lead to recurrence or contralateral reflux after attempts are made at surgical correction of reflux.[75]

Constipation

The distended rectum in constipated children has been suggested to press on the bladder wall and produce an obstruction to bladder outflow that may cause dysfunctional voiding. Urodynamic studies have shown instability of the detrusor muscle in patients with functional constipation and associated enuresis or UTI.[176] Loening-Baucke[90] studied a group of children referred with encopresis and constipation. The history indicated that many were incontinent of urine, and 11 percent had histories of UTIs. When a vigorous regimen to alleviate the constipation was prescribed, a dramatic improvement occurred in the enuresis and the frequency of recurrent UTI.

Kasirga and coworkers studied 38 children with chronic functional constipation and 31 children as the control group. A detailed past and present history of UTIs or symptoms pointing to this diagnosis, enuresis, encopresis, urgency, and urge incontinence was obtained from both groups. Frequency of UTI and urgency was significantly higher in the group with constipation.[70]

Sexual Activity

The well-recognized association in women of acute cystitis with sexual intercourse is reflected in the popular, now perhaps outdated, term *honeymoon cystitis*.[108] This phenomenon is often related to the new onset of sexual activity or a recent change in sexual partners. A novel study of 15 patients with a history of recurrent UTIs

involved daily monitoring for the presence of UTI with dipslides and calendars that recorded episodes of intercourse, menses, and the occurrence of symptoms.[108] Eleven patients experienced 16 infections; 12 infections occurred within 24 hours of engaging in intercourse. In 12 control subjects, three infections occurred, all within 24 hours of having intercourse. The authors concluded that in sexually active women, most UTIs are related to intercourse.

These results were reinforced by a large prospective study from Seattle, Washington, which confirmed that the incidence of symptomatic UTI is high in sexually active young women and that a strong and independent association exists between UTI and recent sexual intercourse, recent use of a diaphragm with spermicide, and a history of recurrent UTIs.[58] Most of these same risk factors, including frequency of sexual intercourse and use of spermicide, were documented as risk factors associated with development of APN in healthy women.[138]

Catheters

In the hospital, urinary catheters are major risk factors for acquisition of nosocomial infection. In adults, the risk for developing an infection is approximately 5 percent per day of catheterization.[107] The usual infecting strains include *Escherichia coli*, *Proteus*, *Pseudomonas*, *Klebsiella*, and *Serratia*. Many strains of bacteria that cause infection display antibiotic susceptibilities that are more resistant than usual. The route of infection may be either intraluminal or periurethral. Bacteremia is an unusual complication of nosocomial UTI. In a study of nosocomial UTIs in a pediatric intensive care unit, catheter-associated UTI occurred at a rate of 0.95 per 100 admissions. Nosocomial UTIs were associated with previous cardiovascular surgery and with urinary tract catheterization of at least 3 days.[99]

PATHOGENESIS

Bacteriology

Most uncomplicated UTIs are caused by members of a large family of gram-negative bacteria known as Enterobacteriaceae. In most instances, the urinary tract becomes infected by the ascending route. Bacteria derived from the fecal flora colonize the periurethral area and gain access to the urethra. The most common bacterial species in primary and recurrent infections is *E. coli*. Other gram-negative species that commonly cause UTI are *Klebsiella*, *Proteus*, *Enterobacter*, and *Citrobacter*, although virtually any enteric organism can be the cause of these infections. Gram-positive bacterial species account for approximately 5 percent of UTIs and primarily include *Staphylococcus saprophyticus* and enterococcal species. After *E. coli*, *S. saprophyticus* is the most common cause of uncomplicated UTIs in teenagers and young adults of both sexes.

Rarely, the urinary tract may become infected hematogenously in the course of a bacteremic infection. This mechanism is thought to account for at least some cases of neonatal UTIs. Increasingly, evidence indicates that even in neonates, most infections occur by the ascending route.

Virulence Factors

The key virulence factor for isolates of *E. coli* is the mechanism by which they attach or adhere to the uroepithelial cell.[62] Bacterial adherence is an essential initiating step in all infections. So-called uropathogenic bacteria, derived from the numerous species found in the fecal flora, can attach to specific receptor sites on the uroepithelium and can bind in a nonspecific manner by electrostatic and hydrophobic bonds.[131] The primary adherence factors encoded by uropathogenic *E. coli*, and many other microbes, are supramolecular, filamentous adhesive organelles known as pili or fimbriae.[167] Some of these pili are referred to as *P fimbriae* because they can recognize and agglutinate erythrocytes of the P1 blood group; this P blood group antigen also is present on human uroepithelial cells. Other common adhesive organelles elaborated by *E. coli* are types 1, 5, and F1C pili encoded by the *fim*, *sfa*, and *foc* operons, respectively.[167]

Evidence to support the notion of the increased pathogenicity or virulence of the P fimbriae comes from studies of *E. coli* recovered from children with infection at different levels of the urinary tract. When *E. coli* strains recovered from patients with pyelonephritis are examined, 76 to 94 percent are P fimbriated; in contrast, strains of *E. coli* recovered from patients with cystitis or asymptomatic bacteriuria are 19 to 23 percent and 14 to 18 percent P fimbriated, respectively.[69,158] Although P fimbriated strains of *E. coli* are common findings in patients with pyelonephritis whose urinary tracts are completely normal, their frequency decreases considerably when strains of *E. coli* are examined from patients with pyelonephritis associated with VUR. Apparently, this virulence characteristic (and others described later) is unnecessary when reflux is present.[92]

The principal adhesin on the tip of the P fimbriae that fosters adherence to the uroepithelial cell is known as the *PapG adhesin*. More recently, 153 *E. coli* organisms recovered from the urinary tracts of infants and children with pyelonephritis were analyzed by polymerase chain reaction for class I, II, and III alleles of the pyelonephritis-associated adhesin gene *papG*. Strains with any class II *papG* alleles were found significantly more often in infants with normal anatomy and function or in infants with clinically insignificant abnormalities than in infants with significant abnormalities (90 of 119 vs. 14 of 34 infants; $p < .001$).[64] This virulence factor is more important when the urinary tract is structurally normal than when anatomic features predispose the individual to infection.

Other virulence factors related to the bacterial species causing UTIs are the K antigen, lipopolysaccharides, hemolysins, colicins, resistance to the bactericidal action of serum, and increased iron-binding capacity. In addition to the immunogenic activity of lipopolysaccharides (activating an intense host response), they have been shown to have direct toxic effects on renal cells via their biologically active component lipid A.[156] The K antigen is a capsular polysaccharide that constitutes an outer

surface of the *E. coli* organism. The capsule has the capacity to impede phagocytosis and to shield the bacteria from lysis induced by complement.[59] Hemolysins are cytotoxic proteins that can damage renal tubular cells in vitro.

Approximately 50 percent of the types of *E. coli* isolated from the urine of patients with APN produce a pore-forming toxin, α-hemolysin. α-Hemolysin damages the cell membrane and may activate apoptosis in renal tubular cells.[18] Colicins, elaborated by "uropathogenic" strains of *E. coli*, kill other bacteria that are in their vicinity. In the presence of human serum, many bacteria are killed after activation of complement. Virulent *E. coli* organisms have the capacity to resist this bactericidal effect of serum. Another virulence factor found in bacteria is their ability to acquire and bind iron. Most bacteria require iron for optimal growth and metabolism and have developed mechanisms to acquire iron when the supply is limited. One strategy to acquire iron is the use of siderophores to scavenge iron from the environment and subsequently concentrate it in the bacterial cytosol.[167] Siderophores such as enterobactin or aerobactin are secreted low-molecular-weight molecules that have a high affinity for ferric (Fe^{3+}) iron. Bacteria retrieve iron bound to siderophores through receptors that facilitate the transport of iron through the bacterial membrane.

After reaching the bladder, P fimbriated *E. coli* organisms can colonize the ureter even in the absence of VUR.[126] Bacterial colonization of the ureter affects ureteral peristalsis, leading to dilation and a physiologic obstruction. This dilation of the ureter and calyces favors a change in the shape of the renal papillae, which facilitates intrarenal reflux of colonizing bacteria at low pressure. APN develops because the receptors for the P fimbriated *E. coli* are present in the collecting duct and proximal tubules.[109,126]

Experimental studies conducted by Roberts[126] have led to a theory of the chain of events involved in the process that ultimately leads to renal scarring. The initial event is the inoculation of the renal parenchyma with bacteria, which leads to an intense inflammatory response. Liberation of proinflammatory cytokines (interleukin-1, interleukin-6, and interleukin-8) is followed by recruitment of inflammatory cells and a second cytokine burst.[67] This inflammation results in the release of toxic enzymes within the granulocytes and tubular lumen. Superoxide is released simultaneously, generating oxygen radicals that are toxic to the bacteria and to the tubular cells.[127] The resultant death of the tubules intensifies and extends the inflammatory process into the interstitium. At the same time, focal ischemia results from the intravascular aggregation of granulocytes and edema.[66] The tissue damage that results from the toxic enzymes, oxygen radicals, inflammatory response, and ischemia culminates in the creation of renal scars.[62,126]

CLINICAL PRESENTATION

Cystitis

Most children older than 5 years of age with cystitis have urgency, frequency, or dysuria.[6] Children who have the urge to urinate may have a history of difficulty in initiating the urinary stream. Occasionally, children may complain of abdominal or suprapubic pain. If fever is present, it is low grade. Suprapubic tenderness may be present on palpation. The urine may be foul smelling and cloudy.

Pyelonephritis

Many children who have APN have impressive chills, spiking fevers, and complaints of back pain.[142] They may have associated gastrointestinal complaints of vomiting and diarrhea, especially vomiting. Lower urinary tract symptoms, such as frequency, urgency, dysuria, and suprapubic discomfort, may or may not be present.

Other findings, such as irritability, poor feeding, vomiting, decreased urinary output, and clinical evidence of dehydration, vary. The youngest children with APN usually have high fever without other localizing features.[53,96,178]

Physical Examination

Features of the physical examination that should be emphasized include (1) an accurate measurement of blood pressure (hypertension may be present in patients who have chronic renal disease), (2) general growth and development (failure to thrive may be a sign of more chronic or recurrent UTI), and (3) a careful abdominal examination (which might reveal tenderness or a mass caused by either an enlarged bladder or an obstructed urinary tract).[154] An effort should be made to elicit the finding of costovertebral angle tenderness in children of all ages. The perineum should be inspected carefully to search for signs of irritation, scars, tears, signs of trauma, labial adhesions, or evidence of vulvovaginitis. In uncircumcised infants, the foreskin may not be retractable, leading to phimosis. A rectal examination should be considered to detect masses or poor sphincter tone, which might be associated with a neurogenic bladder.[154] The lower back should be observed for any lipoma, sinus, pigmentation, or tufts of hair that may be signs of an occult myelodysplasia.

Neurologic examination of the lower extremities and evaluation of the bulbocavernosal reflex often reflect the neurologic integrity of the lower motor neuron reflex arcs. The bulbocavernosus reflex is elicited by squeezing the glans penis or clitoris and observing or feeling a reflex contraction at the external anal sphincter. Absence of this reflex suggests a possible sacral lesion.[5]

Asymptomatic Bacteriuria

A large body of work has been produced dealing with the issue of asymptomatic bacteriuria. Data were accumulated during a long-term study by Kunin[76] of the natural history of recurrent bacteriuria among school-aged girls in a well-defined community in central Virginia. Girls were identified in the first grade and were observed prospectively for 10 years. Each year, approximately 0.5 percent of school-aged girls developed asymptomatic bacteriuria. The cumulative prevalence was 5 percent for the years between entrance to grade school and

graduation from high school. Although it was billed as asymptomatic bacteriuria, approximately one third of the girls did have symptoms, and some were known to have had infection or, rarely, abnormalities of the urinary tract before the first screening.

Just a few years after Kunin[76] began his investigations, a similar study was conducted in Göteborg, Sweden. Beginning in 1970, 19,000 girls a year were screened routinely for bacteriuria in Göteborg schools at ages 7, 11, 14, and 16 years.[88] A significant minority had a history of previous infection or symptoms that were referable to the urinary tract.

Savage and colleagues[134] also studied covert bacteriuria in school-aged girls. In the three studies, the point prevalence of bacteriuria ranged from 0.7 percent[88] to 1.1 percent[76] to 1.6 percent.[134] The risks associated with asymptomatic bacteriuria are difficult to assess from these studies because patients who were truly asymptomatic were difficult to separate from patients with symptoms.

Several prospective studies of infants and school-aged girls from Scandinavia have provided important information regarding the natural history of asymptomatic bacteriuria.[43,165] Most children identified as having asymptomatic bacteriuria among a large cohort of infants (N = 3581) spontaneously cleared the bacteriuria within months. Only 2 of 45 went on to develop symptomatic bacteriuria. In contrast, none of 42 infants who developed symptomatic UTIs had been identified previously as having asymptomatic bacteriuria, suggesting that asymptomatic bacteriuria rarely is a precursor to symptomatic UTI. In addition, prophylactic antibiotics used to treat children with asymptomatic bacteriuria seemed to predispose them to the development of pyelonephritis, usually with microorganisms that had not been present at the outset.[43]

Currently, physicians have little enthusiasm for screening children of any age to discover the presence of asymptomatic bacteriuria. The absence of pyuria in these specimens of urine provides additional evidence that the host is not perturbed by the presence of asymptomatic bacteriuria. The presence of bacteria of low virulence in the urine in asymptomatic patients seems to be protective. These strains apparently prevent invasion by other bacteria and provide a kind of biologic prophylaxis.[43,71]

Rather than screening asymptomatic populations of children, an appropriate approach is vigorous evaluation for the presence of UTIs in febrile children without an obvious focus of infection. In addition, health maintenance examinations should be used as an opportunity to screen for historical information that might suggest the need to collect a urine specimen for culture (Table 39-1). Important items include frequent episodes of unexplained fever, dribbling when urinating, enuresis, encopresis, constipation, urgency, frequency, and dysuria. In addition, it is valuable to know when toilet training was accomplished; frequency of voiding; frequency of stooling; and any apparent difficulties associated with voiding, such as in initiating the urinary stream. The practitioner also should inquire about so-called avoidance maneuvers (e.g., repetitive habitual squirming, crossing of legs, or sitting on heels)[140] and family history of UTI.

TABLE 39-1 **Renal-Focused History and Physical Examination**

History
Age at toilet training
Characteristics and frequency of voiding (urgency, dysuria, dribbling)
Frequency and characteristics of stooling
Family history of renal disease
Habitual squirming
Color and odor of urine
Unexplained episodes of fever
Physical Examination
Temperature
Blood pressure
Abdominal tenderness
Costovertebral angle tenderness
Suprapubic tenderness
Genital examination (irritation, scars, tears)
Rectal examination (sphincter tone, bulbocavernosus reflex)
Lower back (sinus, pigmentation, lipoma, tufts of hair)

DIFFERENTIAL DIAGNOSIS

Infectious

E. coli is the most common cause of infection in the urinary tract for primary infections (in which *E. coli* causes 85% to 90% of infections) and recurrent infections (in which *E. coli* causes approximately 75% of infections). Virtually any other gram-negative enteric bacteria may cause infection. Common etiologic agents include *Klebsiella*, *Proteus*, *Enterobacter*, *Serratia*, and *Pseudomonas*. *Proteus mirabilis* is a common cause of UTIs in some series of boys and in nosocomial UTIs associated with catheterization.[74,112] *Enterococcus* and *Pseudomonas* were the most common cause of nosocomial UTI after *E. coli* in a large series of cases reported from Austria.[122] In young women, *S. saprophyticus* is second only to *E. coli* as a cause of cystitis. Rarely, *Staphylococcus epidermidis* has been reported as a cause of pyelonephritis in young boys with anatomic abnormalities of the urinary tract.[41]

Acute lobar nephronia is a localized nonliquefactive inflammatory infection of the kidney that has also been called acute focal bacterial nephritis.[19,128] It represents the midpoint in the spectrum of acute uncomplicated pyelonephritis and renal abscess. From a clinical perspective, it may be signaled by protracted fever before and after diagnosis and may warrant a longer duration of antimicrobial treatment than uncomplicated APN. The diagnosis depends on the performance of an enhanced computed tomographic (CT) scan. The bacterial etiology is the same as for other cases of APN.

Xanthogranulomatous pyelonephritis is a rare, chronic, suppurative renal infection. Although it can occur at any age, it typically involves middle-aged women. Cases in children have been reported across all age groups, including infants.[1,40,179] The patient usually presents with what appears to be an acute UTI, caused most often by *E. coli*

or *Proteus* spp. Evaluation of the patient usually reveals a unilateral enlargement of the kidney, often accompanied by urolithiasis and sometimes a staghorn calculus. The differential diagnosis of the mass lesion includes neuroblastoma, Wilms tumor, tuberculosis, and renal carcinoma. The lesion is characterized histologically by granulomas, abscesses, and lipid-laden foam cells. Nephrectomy is the usual means of management.

In the context of bacteremia or septicemia, occasionally the blood culture and the urine culture are positive for the same bacterial species. In these instances, the kidney has been seeded as part of a hematogenous dissemination. Any organism that is responsible for sepsis, such as *Haemophilus influenzae* type b, *Neisseria meningitidis*, *Neisseria gonorrhoeae*, *Staphylococcus aureus*, *Streptococcus pneumoniae*, or *Streptococcus pyogenes*, may be found in the urine.

Anaerobic infections of the urinary tract are rare occurrences in children despite the high density of gram-positive and gram-negative anaerobes in the fecal flora; this fact relates to the probable lack of adherence of these bacterial species to the uroepithelium. Anaerobic infections of the urinary tract should be suspected when organisms are seen on Gram stain but do not grow in conventional culture or when the urine of symptomatic children shows no bacterial growth.[13] Another unusual infecting agent that should be suspected in instances in which the Gram stain of the urine shows gram-negative rods but the urine culture is negative is *H. influenzae*.[103]

Fungal infections of the urinary tract usually are caused by *Candida* spp., but they also may be caused by *Cryptococcus neoformans*, *Aspergillus* spp., and the endemic mycoses.[152] Candiduria is an increasingly common form of nosocomial infection that may involve any level of the urinary tract.[50,118] It often occurs in immunosuppressed patients, especially patients who are receiving broad-spectrum antibiotics for treatment of documented or undocumented systemic infections. In many immunosuppressed patients, the infection is complicated by the presence of an indwelling urinary catheter.

Viruses also may cause infection of the urinary tract. For the most part, these infections involve the bladder rather than the kidney, although infection of any part of the urinary tract may occur. The principal etiologic agents are adenoviruses, enteroviruses, coxsackieviruses, and echoviruses. Mumps virus and hepatitis viruses occasionally have been implicated. Type 11 adenovirus has been the most common cause of acute hemorrhagic cystitis in school-age boys; type 21 also has been documented to be a cause of infection in this age group. In immunosuppressed patients, especially children who have undergone bone marrow transplantation or are recipients of kidney transplants, BK polyomavirus and adenovirus may cause hemorrhagic cystitis.[20,85,113]

Granulomatous cystitis is the histopathologic description of cystitis caused by *Mycobacterium tuberculosis* and by schistosomiasis and other parasitic infections. Granulomas formed in response to certain parasites, such as *Toxocara* and microfilariae, also may contain numerous eosinophils. *Enterobius vermicularis* infection occasionally leads to signs and symptoms of cystitis and inflammatory changes of the bladder wall.

Infectious urethritis caused by *N. gonorrhoeae* or *Chlamydia trachomatis* is a common cause of symptoms suggestive of UTI. In addition, any etiologic agents of vulvovaginitis may cause inflammation of the distal urethra, with urgency, frequency, or dysuria; they include *Candida* spp., *Gardnerella vaginalis*, *Trichomonas vaginalis*, *S. pyogenes*, *S. pneumoniae*, *H. influenzae*, *C. trachomatis*, *Shigella* spp., and *Yersinia enterocolitica*.

Noninfectious

Urethral symptoms, such as urgency, frequency, and dysuria, may be caused by any factor or process that gives rise to inflammation in the lower urinary tract. Examples include mechanical irritation (which might result from insertion of foreign bodies, migration of pinworms, or masturbation) and chemical irritation (which might arise from bubble baths or shampoos). Chemical cystitis has been reported from the inadvertent insertion of a vaginal contraceptive suppository (nonoxinol 9) into the bladder. Pharmacologic causes of urethral symptoms include cyclophosphamide and methenamine mandelate, both of which can lead to inflammatory changes in the urinary bladder. Several other agents used in the topical treatment of bladder cancer have been noted to cause cystitis.

DIAGNOSIS

Collection of a Urine Specimen

Proper collection of a urine specimen is crucial to facilitate interpretation of the culture. In toilet-trained children, a midstream clean-catch specimen is appropriate for evaluation. When this specimen is used, the definition of significant bacteriuria is 10^5 colony-forming units (CFU)/mL or more. The child is asked to void into the toilet. Straddling the commode in a reverse position creates a natural separation between the urethra and the vulva. Cleansing of the perineum does not result in less contamination of the specimen and is no longer encouraged.[136] The child is asked to begin voiding. A second or two after the void has been initiated, a sterile cup is passed into the stream. The hope is that the initial void succeeds in washing out the distal urethra, the site from which the urine specimen is most likely to be contaminated.

If the child is not toilet trained, a specimen may be collected by urethral catheterization or suprapubic aspiration. When the urine is collected by urethral catheterization, the perineum is cleaned with 1 percent iodine. A properly sized catheter (10 or 12 French) or a size 5 feeding tube may be used. The catheter is lubricated and inserted into the urethra and threaded a short distance. The first few drops of urine should be collected outside the sterile container. This part of the specimen is the most likely to be contaminated with fecal flora from the distal urethra; these bacteria are not eliminated by the process of perineal cleansing. The remaining urine is collected in a sterile container and sent to the laboratory. When a urine specimen is collected by urethral

catheterization, significant bacteriuria is defined as 50,000 CFU/mL or more.[56] This method is preferred when a small volume of urine in the bladder is anticipated and collecting a specimen of urine is necessary so that antibiotic therapy can be initiated. Unfortunately, there is a high likelihood that even a urine sample obtained by catheter will be contaminated (14%), especially in infants younger than 6 months of age, when the catheterization is difficult, and in uncircumcised boys.[173] Use of bladder ultrasonography increases the success of the procedure.[17]

An alternative to urethral catheterization is suprapubic aspiration. Some physicians contend that catheterization is less traumatic than suprapubic aspiration.[154] There is modest evidence that when suprapubic aspiration is performed in very young infants it may be associated with greater discomfort than catheterization of the urine. The procedure can be done in children of any age; it has been used to obtain specimens of urine in pregnancy.[100] Urine culture specimens obtained by suprapubic aspiration are easy to interpret because the usual source of contamination, the distal urethra, has been bypassed. The presence of any bacteria in a specimen collected by suprapubic aspiration is significant, although most samples contain 10^5 CFU/mL or more. Use of bedside ultrasonography increases the likelihood of a successful procedure.[104]

To perform a suprapubic aspiration, the patient is placed in a supine position with the lower extremities flexed (Fig. 39-1 and Table 39-2). Iodine and alcohol are used to clean the suprapubic area. The symphysis pubis is located with the index finger. A 3-mL syringe is attached to a 1½-inch, 22-gauge needle. A spinal needle (2½- or 3-inch, 21-gauge) can be used in older patients. The needle is passed in the midline about 1.5 cm above the symphysis pubis. It is angled 10 to 20 degrees from the vertical, pointing in a slightly cephalad direction (Fig. 39-2). Negative pressure is applied while the needle is inserted. The procedure is most likely to be successful when the infant can be encouraged to drink and the diaper has been dry for at least 60 minutes before the procedure is done. The success rate of suprapubic aspiration can be improved with the use of a portable ultrasound device.[35] If the suprapubic aspiration is unsuccessful, a catheterized specimen should be obtained. Complications of suprapubic aspiration are rare and include formation of a hematoma, perforation of the bowel, and formation of a suprapubic abscess.[120] Suprapubic aspiration is contraindicated if the patient has a bleeding diathesis.

The last method of urine collection is the bag technique. The perineum is washed with soap and water and allowed to dry. A sterile plastic bag is attached. The bag is removed as soon as the patient voids. If the patient has not voided in 20 minutes, the bag is removed, the

TABLE 39-2 Suprapubic Aspiration Technique

Step 1	Child should not have voided within 1 hour of the procedure.
Step 2	Restrain the infant in a supine, frog-leg position.
Step 3	Clean the suprapubic area with povidone-iodine and alcohol.
Step 4	Identify the site of puncture at 1 to 2 cm above the symphysis pubis in the midline.
Step 5	Use a 22-gauge, 1½-inch needle (with 3-mL syringe attached to it) and puncture at 10- to 20-degree angle of the true vertical aiming cephalad; a second attempt can be made at a similar angle aiming caudad.
Step 6	Exert suction gently as the needle is advanced until urine enters syringe; aspirate urine with gentle suction. If urine is not obtained, further trials are unlikely to be successful.

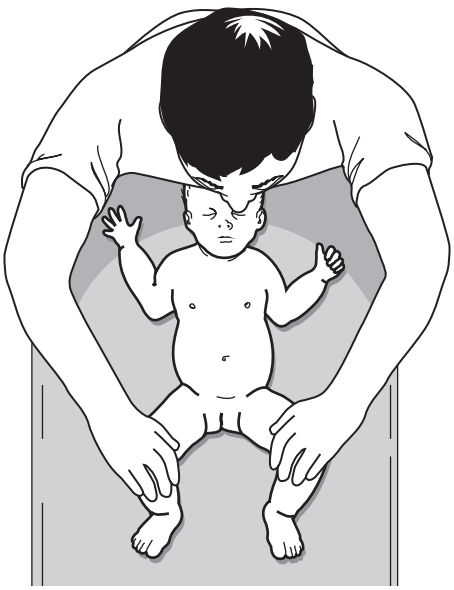

FIGURE 39-1 ■ Suprapubic aspiration technique, position of patient.

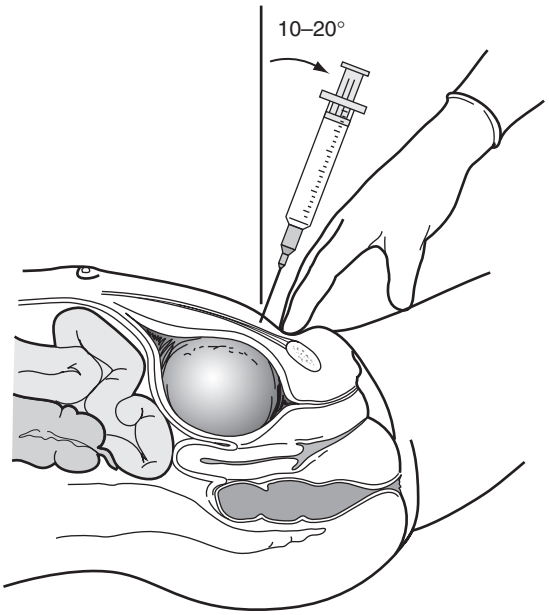

FIGURE 39-2 ■ Suprapubic aspiration technique, position of needle.

perineum is cleaned again, and a new bag is attached. If this procedure is followed meticulously, a reasonable specimen can be collected. This specimen is susceptible to contamination from periurethral flora,[135] however, and the technique is not recommended if the patient appears ill and antibiotic therapy needs to be started immediately after the specimen of urine is collected. The results of the culture of a bagged specimen are useful only if they are negative. If the culture is positive, a second specimen must be collected by a more reliable method.[3]

Diagnosis of Urinary Tract Infection

The diagnosis of UTI hinges on the results of culture of a properly collected urine specimen. Disagreement within the literature is substantial regarding the definition of significant bacteriuria.[37] As indicated in the previous section, the definition of UTI varies according to the method by which the urine is collected. This variability in definition acknowledges that although the bladder urine is regarded as a sterile body fluid, contamination of the urine specimen may occur as it passes through the urethra. The distal urethra frequently is colonized with coliforms derived from the gastrointestinal tract. The only urine specimen that bypasses the urethra and is free of contamination is obtained by suprapubic aspiration. When a specimen is collected by this technique, any colony count of coliforms is significant.[178]

In urine that is collected by a midstream clean-catch method, significant bacteriuria is defined, most stringently, by the recovery of 100,000 CFU/mL or more (Table 39-3). For specimens of urine obtained by catheter, significant bacteriuria is defined as 50,000 CFU/mL or more. In each of these instances, physicians recognize that although urine specimens containing lower colony counts rarely may represent true infection, for the most part lower colony counts usually are the result of contamination of the specimen.[56]

Specimens of urine usually are inoculated onto two different kinds of solid media—one that supports the growth of only gram-negative enteric bacteria (e.g., MacConkey agar) and another that supports gram-positive and gram-negative bacteria (e.g., 5% sheep blood agar), with use of a 0.001 calibrated loop. Colonies are counted the next day (18 hours later), and the total is multiplied by 1000 to determine the colony count. The results of the urine culture are unavailable during the practitioner's first encounter with the ill child. Consequently, there is great interest in the development of a method that would predict the results of the urine culture so that appropriate antimicrobial therapy could be initiated presumptively at the time of the initial encounter. Microscopic methods (to evaluate pyuria and bacteriuria) and biochemical tests (which can be evaluated with a dipstick) have been evaluated and will be discussed. However, the performance of urine culture is mandatory because no rapid urine test is sufficiently sensitive to identify all children with UTI.[170]

TABLE 39-3 **Urinary Tract Infection—Definitions**

Method of Collection	Colony Count (CFU/mL)

Catheter	$\geq 5 \times 10^4$
Suprapubic	Any

CFU, colony-forming unit.

Microscopy

Two surrogate markers for UTI on microscopic assessment are pyuria and bacteriuria. A problem in assessing pyuria and bacteriuria has been the issue of the definition of significant microscopic pyuria and bacteriuria. How many white blood cells (WBCs) in the urine are too many? Should the specimen of urine that is examined be centrifuged or uncentrifuged? How should the WBCs in a specimen of urine be enumerated? Should the number of WBCs on a centrifuged specimen be enumerated as the number per high-power field, or should they be enumerated on a counting chamber as the number of cells per cubic millimeter, as they would be in a sample of cerebrospinal fluid? If the urine is centrifuged, additional variables are introduced: the initial volume of urine, the duration of the spin, and the volume of urine used to resuspend the sediment. All of these variables influence substantially the enumeration of WBCs per high-power field, especially the volume used to resuspend the sediment.

Methods to assess bacteriuria also have raised issues of definition. Should bacteriuria be assessed on a centrifuged specimen or an uncentrifuged specimen, and should the bacteria be evaluated on a wet mount or a Gram-stained specimen? Should bacteria be enumerated as the number per high-power field?

The standard definition of pyuria in the pediatric literature has been 5 WBCs per high-power field on a centrifuged specimen. Traditionally, microscopic bacteriuria has been expressed as the number of bacteria per high-power field on a Gram stain of a centrifuged specimen of urine. Several investigations undertaken by Hoberman and colleagues[55] have shown, however, that a so-called enhanced urinalysis has greater sensitivity, specificity, and positive predictive value than the standard urinalysis. An enhanced urinalysis is performed on an uncentrifuged sample of urine that has been obtained by catheter. The urine is placed on a counting chamber, and the cells are enumerated as the number per cubic millimeter. A Gram stain is performed in a manner that standardizes the number of drops of urine that are assessed and the number of oil immersion fields that are reviewed.

An enhanced urinalysis is considered to be positive when 10 WBCs/mm^3 or more are present and at least one gram-negative rod in 10 oil immersion fields is present. This definition of significant pyuria is much more sensitive than were previous definitions, and it has performed well for numerous investigators and in neonates and in older infants.[49,86-88,178] A systematic review of the existing literature to assess the performance of rapid diagnostic tests for UTI concluded that use of the traditional definition of pyuria (>5 WBCs per high-power

field on a centrifuged specimen) is sufficiently poor that it cannot be recommended for making a presumptive diagnosis of UTI.[37] Huicho and coworkers[61] also performed a meta-analysis of urine screening tests to determine the risk for UTI in children. This study concluded that pyuria of at least 10 WBCs/mm^3 and bacteriuria are best suited for assessing the risk for UTIs in children. The most recent meta-analysis concluded that detection of bacteriuria by microscopy with Gram stain is the single best test and, if available locally and reported rapidly, is the optimum guide to empirical treatment of children with antibiotics.[170]

Automated methods to perform urinalysis are being used in many hospitals and laboratories. The most updated automated image-based urinalysis system, the iQ200, received clearance from the U.S. Food and Drug Administration more recently. The system uses flow imaging analysis technology and so-called Auto Particle Recognition (APR) software to classify particles found in an uncentrifuged urine specimen based on multiple parameters. Images are stored and can be viewed later on the workstation screen, eliminating the need for manual microscopy in most cases.[160] The iQ200 provides for a rapid turnaround time, and results correlate well with manual methods, especially for red blood cells, WBCs, and squamous epithelial cells.[77,89]

Pyuria is not specific for UTI. In numerous other conditions, including fever, streptococcal infections, and Kawasaki disease, and after exercise, WBCs are found in the urine. Finding pyuria does not ensure that an infection of the urinary tract is present. Despite reports to the contrary, finding true UTI without pyuria is unusual.[162] Generally, inflammation is expected to accompany infection. The absence of pyuria in children with UTIs is rare; it may occur when a child is being evaluated so early in the clinical course of the infection that the inflammatory response has not yet developed. It also may occur when a child is experiencing an episode of asymptomatic bacteriuria.

The most likely explanation for significant bacteriuria by culture in the absence of pyuria is a contaminated specimen. In most cases when UTI has been reported to occur in the absence of pyuria, the definition of pyuria has been at fault. The requirement for 5 WBCs per high-power field on a centrifuged specimen corresponds to approximately 25 WBCs/mm^3; this is too stringent a requirement, with a low sensitivity for the detection of UTIs in infants and children.

Urine Dipsticks

Urine dipsticks (or reagent strips) have been used to indicate the presence of leukocyte esterase (as a surrogate marker for pyuria) and urinary nitrite (which is converted from dietary nitrates by the presence of gram-negative bacteria in the urine). The conversion of dietary nitrates to nitrites by bacteria takes approximately 4 hours. The test result is most likely to be positive when the urine tested is the first morning void (representing a urine that has incubated in the bladder overnight) or a urine that has been in the bladder for at least 4 hours (e.g., obtained from an older child who may hold urine in the bladder for several hours at a time). Most gram-positive cocci will not produce nitrites.

The performance characteristics of leukocyte esterase and nitrites vary according to the definition used for a positive urine culture, the age and symptoms of the population being studied, and the method of urine collection. A nitrite test, although not a sensitive marker in children, is helpful when the result is positive because it is highly specific. A negative nitrite test result has little value in ruling out UTI, however.[25] The leukocyte esterase test has an average sensitivity of 83 percent.[26] It can have a sensitivity of 94 percent in settings in which UTIs are suspected clinically and a sensitivity of 52.9 percent when it is performed on febrile children, most of whom do not have a UTI.[56] The specificity of leukocyte esterase (average, 72%; range, 64% to 92%) generally is not as good as the sensitivity, reflecting the nonspecificity of pyuria in general. A positive leukocyte esterase test result should be interpreted with caution, depending largely on the population being evaluated.[25]

If both leukocyte esterase and nitrites are positive, the sensitivity and specificity are very high. The combination of a positive leukocyte esterase and nitrate predicts a positive urine culture very accurately; and when both are negative, the likelihood of UTI is low.[124]

Determining the Site of Infection

Urinalysis is useful for detecting infection but not for determining the location of the infection within the urinary tract (i.e., upper tract vs. lower tract). To determine the site of infection (i.e., kidney vs. bladder), many investigations of the discriminatory ability of C-reactive protein, erythrocyte sedimentation rate, and total peripheral WBCs have been performed. Several studies have evaluated the accuracy of procalcitonin levels compared with C-reactive protein levels to predict renal involvement among children with febrile UTIs.[8,33,115,121,151] These studies showed that serum procalcitonin concentrations, measured with either an immunoluminetric quantitative test or a rapid semiquantitative test, diagnosed APN with a sensitivity of 70.3 to 94.1 percent and a specificity of 82.6 to 93.6 percent. The specificity of procalcitonin was always higher than that of C-reactive protein, and a highly significant correlation was noted between elevated procalcitonin levels and severity of renal involvement as measured by dimercaptosuccinic acid (DMSA) scintigraphic scores.[118]

In a recent meta-analysis, 12 studies representing 526 patients with UTI (10% with VUR of grade III or higher) were included.[82] The sensitivity of procalcitonin greater than or equal to 0.5 mg/mL as an indicator of VUR of grade III or higher was 83 percent (95% CI, 71 to 91) with a 43 percent specificity rate (95% CI, 38 to 47). In the subgroup of children with positive results on DMSA scan, procalcitonin greater than or equal to 0.5 mg/mL was also associated with high-grade VUR (adjusted odds ratio, 4.8; 95% CI, 1.3 to 17.6). More research is necessary before measurement of procalcitonin becomes routine in the evaluation of children with UTI.[81]

TABLE 39-4 **Imaging Procedures in Children with Urinary Tract Infection**

1. Renal ultrasonography
2. Renal scintigraphy
3. Magnetic resonance imaging
4. Voiding cystourethrography
5. Computed tomography

Imaging

The recommendations for performing imaging procedures on children with a diagnosis of UTI have undergone change and remain somewhat controversial. The imaging studies that usually are considered are renal ultrasonography, contrast voiding cystourethrography (VCUG) to detect VUR, renal cortical scintigraphy, and magnetic resonance imaging (MRI) (Table 39-4).

Renal Ultrasonography

The renal ultrasound examination has replaced intravenous pyelography as a means to assess the gross anatomy of the urinary tract. Generally, ultrasonography has been performed promptly after diagnosis of the UTI has been made. It is a noninvasive test that can describe the size and shape of the urinary tract, the presence of duplication and dilation of the ureters, the presence of ureteroceles, and the existence of gross anatomic abnormalities such as a horseshoe kidney.[3] It is not sensitive enough, however, to signal consistently the presence of hydronephrosis, hydroureter, VUR, or renal scarring.[29] When ultrasonography was compared with intravenous pyelography for the detection of renal scars, wide interobserver variations were noted, with sensitivity ranging from 40 to 90 percent.[36]

Widespread application of prenatal ultrasonography has reduced the prevalence of previously unsuspected obstructive uropathy in infants, but the consequences of prenatal screening with respect to the risk for renal abnormalities in infants with UTIs have not yet been well defined.[3] There is considerable variability in the timing and quality of prenatal ultrasonograms, and the report of "normal" ultrasonographic results cannot necessarily be relied on to dismiss completely the possibility of a structural abnormality unless the study was a detailed anatomic survey (with measurements), was performed during the third trimester, and was performed and interpreted by qualified individuals. Unfortunately, a negative prenatal ultrasound evaluation does not significantly alter the probability of finding an abnormality on a postnatal ultrasound evaluation after a UTI.[72]

Some investigators have questioned whether routine performance of renal ultrasonography is essential.[52] Several studies of a large number (N = 561) of young children with their first febrile UTI disclosed that abnormalities found on ultrasound evaluation were infrequent and rarely influenced management.[54,177] In the most recent investigation of this question, the renal ultrasound study was abnormal in 23 of 155 (14.8%) children.[63] Management of 4 patients was changed by the results. Because of the seriousness of the uncommon but potentially correctable abnormalities in 1 to 2 percent of children with their first UTI and because ultrasonography is noninvasive and poses minimal risk, the American Academy of Pediatrics has recommended performance of renal and bladder ultrasonography in all febrile infants with a UTI.[3]

The timing of renal and bladder ultrasonography depends on the clinical situation. The imaging study is recommended during the first 2 days of treatment to identify serious complications such as renal or perirenal abscesses or pyonephrosis associated with obstructive uropathy when the clinical illness is unusually severe or substantial clinical improvement is not occurring. For febrile infants with UTIs who demonstrate substantial clinical improvement, however, imaging does not need to occur early during the acute infection and the results can even be misleading. Changes in the size and shape of the kidneys and the echogenicity or renal parenchyma attributable to edema also are common during acute infection. The presence of these abnormalities makes it inappropriate to consider renal and bladder ultrasonography performed early during acute infection to be a true baseline study for later comparisons in the assessment of renal growth. An optimum time to perform the ultrasound is one week after diagnosis.

Renal Scintigraphy

In patients with presumed APN, renal scintigraphy with technetium-99m DMSA or technetium-99m glucoheptonate has been shown to be the most practical and reliable method for detecting APN.[140] DMSA and glucoheptonate are amino acids that are cleared by the renal tubules. When these amino acids are labeled with technetium and injected intravenously, they can be used to create an image of the kidney, which reflects vascular flow and tubular function (Fig. 39-3). In experimentally induced APN in piglets, the DMSA scan had a sensitivity of 87 percent and a specificity of 100 percent in showing lesions consistent with APN compared with histology as the gold standard.[132]

In most patients with APN, renal scintigraphy performed during the acute phase of the illness shows a decreased uptake of DMSA (Fig. 39-4). High-resolution pinhole images of the kidney reveal focal, multifocal, or diffuse areas of decreased uptake of isotope in the kidney without loss of volume and with maintenance of the contour of the kidney.[140] DMSA renal scintigraphy can be used to localize the level at which the urinary tract is infected, specifically distinguishing between acute cystitis and APN with a sensitivity of slightly less than 90 percent. Rarely, a patient may have classic signs and symptoms of APN but renal scintigraphy does not show the usual findings.[31] Nonetheless, renal scintigraphy is the most sensitive study to indicate the presence of APN.

The DMSA and glucoheptonate scans also can be used to indicate the presence of renal scars that result from an episode of APN. The scar is indicated by an area in which uptake of the radioisotope is decreased (Fig. 39-5). In this case, the contour of the kidney is not preserved. Scarring

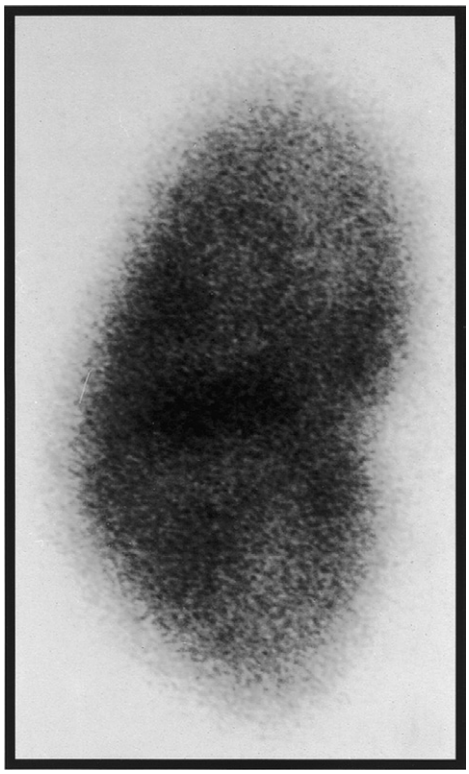

FIGURE 39-3 ■ Normal renal scintigram.

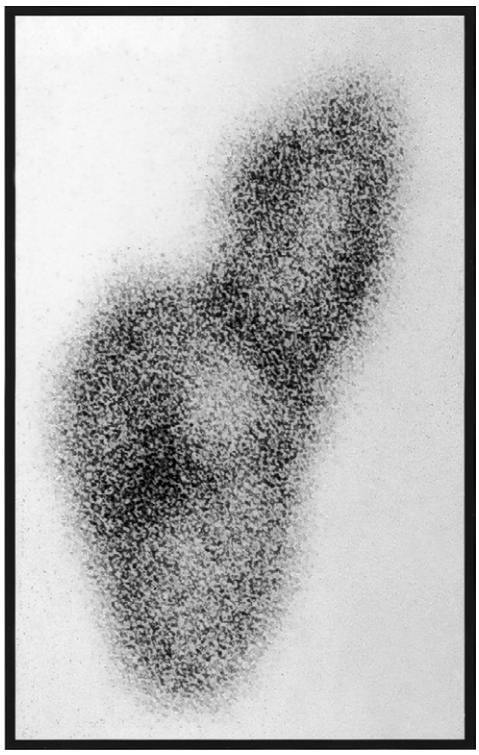

FIGURE 39-5 ■ Scintigram showing a renal scar with loss of the normal contour.

FIGURE 39-4 ■ Scintigram showing acute pyelonephritis, manifesting as a photon-deficient area in the upper pole.

also may be indicated by an overall reduction of the size of the kidney. Hoberman and colleagues[52] prospectively evaluated 309 infants who were 1 to 24 months old with their first febrile UTI. An initial DMSA scan was performed on all infants and showed that 61 percent (190 of 309) had findings compatible with APN and only 1 infant had evidence of previous scars. Repeat scintigraphic scanning was done 6 months after entry in 89 percent to detect renal scarring. A small percentage of renal parenchymal involvement (mean 8.2%) was noted in 9.6 percent of the infants. All infants whose initial scans were normal had normal scans at follow-up.

DMSA scintigraphy has been suggested as the preferred imaging study to evaluate a child with a first febrile UTI rather than ultrasonography or VCUG.[42,47] A strategy to perform VCUG only in patients with an abnormal DMSA scan has been proposed. The rationale is based on the high negative predictive value of a normal DMSA for high degrees of reflux (III to V) and rarity of renal scarring when the initial DMSA is normal.[72] Reflux definitely may be present, however, when DMSA scans are normal (30 of 99 in Hoberman's data).[52] Absence of scarring may be attributable to the effect of antibiotics.

Magnetic Resonance Imaging

MRI can be used to detect the presence of APN. Two studies by Lonergan and colleagues[94,116] showed a sensitivity and a specificity of MRI that are equal to and perhaps even greater than those of renal scintigraphy

with DMSA. In both instances, the best pulse sequence to show areas of APN with MRI was gadolinium-enhanced, fast spin-echo inversion recovery. These results have been confirmed by others.[80] Several investigators have urged, however, that MRI not become a screening test for children with UTIs until the detection of minor changes in the renal parenchyma (by either DMSA or MRI) has been proved to be of clinical importance.[80,93] The time and sedation requirements for MRI render it an unattractive choice for routine management.

Voiding Cystourethrography

Two types of cystography are available for the diagnosis of VUR: fluoroscopic contrast VCUG and radionuclide cystography. Contrast VCUG has excellent anatomic resolution and provides detailed images of the bladder and the urethra. It can be used specifically to label the degree of reflux (according to the international classification)[78]; to look for trabeculations, diverticula, or ureteroceles of the bladder; and to outline the urethra (which is essential to identify posterior urethral valves causing obstruction). Radionuclide cystography provides less anatomic detail and is most useful when urethral disease is not suspected and when the patient has no history of voiding dysfunction. It is used to observe patients who are known to have reflux (to assess whether reflux is still present) and can be used for screening purposes in siblings of children with reflux and in children of adults known to have had reflux. Compared with conventional contrast VCUG, the amount of radiation exposure is reduced substantially when the radioisotope is used.

The international classification of reflux is a universally used system involving five degrees of reflux.[78] Grade I is reflux into the distal ureter; grade II is reflux into the proximal ureter; and grades III, IV, and V are reflux with mild, moderate, and severe dilation of the pelvis and calyces (Fig. 39-6).

VCUG is performed on children who have experienced a symptomatic UTI to determine the presence of VUR. Children who have VUR are at risk for developing reflux nephropathy—permanent renal damage secondary to the reflux of infected urine into the kidney. Because reflux often resolves spontaneously over the course of several years, the purpose of identifying a child with VUR in the past was to recommend antibiotic prophylaxis until the reflux either had resolved spontaneously or, in cases of high degrees of reflux, had been corrected surgically.

Although imaging of children with UTI has been routine, little evidence exists that diagnostic imaging of children after their first UTI results in prevention of renal scarring, hypertension, or renal failure.[21] The value of identifying abnormalities on the renal ultrasound or VCUG is predicated on the benefits of treatment for these findings, which is a subject of recent controversy.[72] If studies can show with certainty that antibiotic prophylaxis to prevent UTIs in children with VUR is superior to placebo in the prevention of renal scarring, the necessity and importance of performing VCUG would be established. Such a study was funded by the National Institutes of Health to begin in 2007[38] (see later section on VUR under Treatment). In the past 5 years, several studies have been published casting doubt on the effectiveness of antibiotic prophylaxis.[12,32,102,117,130]

Computed Tomography

In general, CT of the kidneys is not recommended. However, when the clinical response to treatment is sluggish, this study is occasionally performed. Both xanthogranulomatous pyelonephritis and lobar nephronia are best imaged with this technique.[19,40]

TREATMENT

Antibiotics for Treatment of Acute Infection

The treatment of UTI is influenced by the age of the patient, the probable site of infection (cystitis or APN), the degree of toxicity, and the likelihood of adherence to the treatment regimen. Oral antimicrobial therapy is appropriate for children with cystitis and for older children with suspected APN who are neither toxic nor

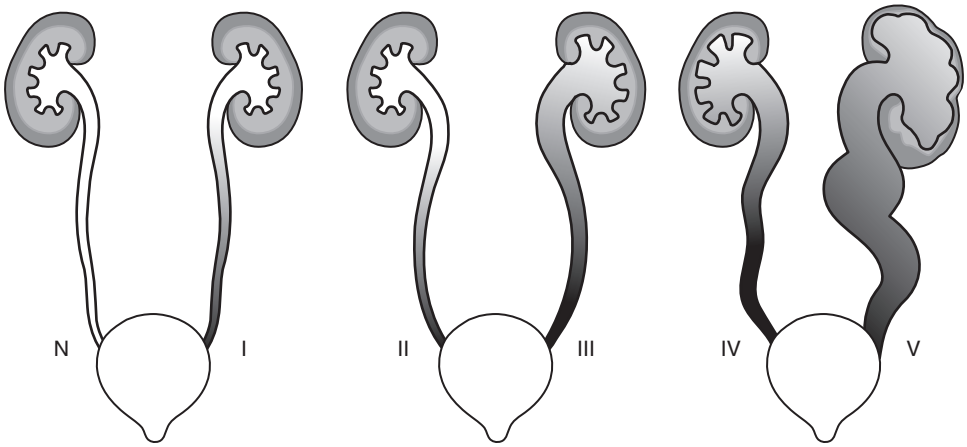

FIGURE 39-6 ■ International classification of vesicoureteral reflux.

TABLE 39-5 **Antibiotic Treatment**

Drug Name	Dosage
Oral	
Amoxicillin + potassium clavulanate	45 mg/kg/day in two divided doses
Cefuroxime	30 mg/kg/day in two divided doses
Cefprozil	30 mg/kg/day in two divided doses
Cefixime	10 mg/kg/day in one dose
Cefpodoxime	9 mg/kg/day in one dose
Ceftibuten	10 mg/kg/day in one dose
Cefdinir	14 mg/kg/day in one dose
Trimethoprim-sulfamethoxazole	10 mg/kg/day (trimethoprim) in two divided doses
Parenteral	
Ampicillin + sulbactam	200 mg/kg/day in four divided doses
Cefuroxime	150 mg/kg/day in three divided doses
Cefotaxime	200 mg/kg/day in four divided doses
Ceftriaxone	80 mg/kg/day in one dose
Ceftazidime	150 mg/kg/day in three divided doses
Cefepime	100 mg/kg/day in two divided doses
Gentamicin	7.5 mg/kg/day in three divided doses

vomiting. The more complex issue is the management of a young infant with high fever in whom the likely diagnosis is APN. These children traditionally have been admitted to the hospital for parenteral administration of antibiotics.

Numerous choices of oral antimicrobial agents are available for patients who have presumed cystitis (Table 39-5). Alternatives include amoxicillin + potassium clavulanate; second-generation cephalosporins, such as cefuroxime and cefprozil; third-generation cephalosporins, such as cefixime, cefpodoxime, ceftibuten, and cefdinir; and the combination agent trimethoprim-sulfamethoxazole. Generally, neither amoxicillin nor first-generation cephalosporins are recommended for first-line therapy because 30 to 50 percent of *E. coli* now are inherently resistant to these agents. Because of some geographic variability in the prevalence of resistance, the practitioner should check with local infectious disease specialists to verify these susceptibility patterns.

In an older patient who appears ill but is not toxic, a repeated visit or telephone follow-up is indicated to ensure that recovery is progressing as predicted. If fever is present, the patient generally becomes afebrile within 1 or 2 days, although occasionally it may take longer. If other indices of recovery, such as general well-being, appetite, and playfulness, are improving appropriately, the persistence of fever is not alarming. If susceptibility test results are available and the organism causing infection is susceptible to the antimicrobial agent being used, repeating the urine culture after 24 hours is unnecessary.[54] The rapid sterilization of urine is a testimony to the fact that virtually all the antibiotics that are used to treat UTIs are concentrated in the kidney and excreted in the urine.

Duration of treatment for patients who are presumed to have cystitis has been controversial. Conventional recommendations are for 7 to 10 days of antimicrobial therapy. Short courses of therapy, varying from single-dose regimens to 3- or 4-day courses, have been evaluated with mixed results. The potential advantages of short-course therapy include the likelihood of improved adherence to the drug regimen; lower cost of drug; and fewer undesirable side effects, including less alteration of normal flora.[143] A meta-analysis (and the most comprehensive review of the data) was performed by Tran and coworkers[155] after review of 22 published trials and a total of 1279 patients. Amoxicillin in a single dose and trimethoprim-sulfamethoxazole as either a single dose or a 3-day regimen were the short-course regimens most commonly evaluated. The authors found that short-course antimicrobial therapy is less effective than therapy of conventional duration, largely because of the ineffectiveness of single-dose amoxicillin. A 3-day course of trimethoprim-sulfamethoxazole was an effective alternative to the standard course of treatment.

A more recent meta-analysis evaluated 10 trials in 652 children with lower tract UTIs.[57] No significant difference was found in the frequency of positive urine cultures between short-duration (2 to 4 days) and standard-duration (7 to 14 days) oral antibiotic therapy for UTIs in children 1 to 15 months after treatment. In children with clear evidence of cystitis without APN, short-course therapy may be acceptable.[161]

Management of a young infant with presumed APN has been controversial. A study conducted by Hoberman and colleagues[54] compared oral therapy with cefixime (for 14 days) with a combination of intravenous therapy with cefotaxime (for 3 or 4 days) plus oral cefixime for 9 to 10 days. Children were eligible for this study if they were 1 to 24 months of age and presented to the physician with temperature greater than 38.3°C (100.9°F) and were found to have a positive enhanced urinalysis (≥10 WBCs/mm^3 and 1 organism/10 oil immersion fields). After blood and urine cultures, complete blood cell count, C-reactive protein determination, and erythrocyte sedimentation rate were performed, the children were randomly assigned to treatment groups. Outcome was evaluated with regard to the short-term measures of sterilization of the urine and time to defervescence and the long-term measures of reinfection and scarring 6 months after the initial infection. No statistically significant differences in any outcome were found.

Hodson and colleagues[101] performed a systematic review of the treatment of APN in children. They assessed 23 trials of 3295 children aged up to 18 years with proven UTIs and APN. Their results suggested that children with APN could be treated effectively with oral antibiotics (cefixime, ceftibuten, and amoxicillin-clavulanate) or with short courses (2 to 4 days) of intravenous therapy followed by oral therapy to complete a 10-day course. If intravenous therapy is chosen, single-dose treatment

daily with an aminoglycoside is safe and effective.[101] If the diagnosis of lobar nephronia is made secondary to a sluggish response to antimicrobial therapy, 2 or 3 weeks of antibiotic therapy (dependent on the pattern of abnormality seen on the CT scan) is recommended rather than a 10-day course.[19]

Corticosteroids

A 2011 publication examining the potential role of corticosteroid therapy, as an adjunct to antibiotics, in the acute phase of APN suggests a beneficial effect.[60] Nineteen patients treated with methylprednisolone were compared with 65 in the placebo group. Adjunctive oral corticosteroids reduced the occurrence and severity of renal scarring in children with APN. Larger studies must be performed before this strategy is adopted.

Dysfunctional Voiding

If a history of dysfunctional voiding is obtained, a behavioral modification approach may be helpful. The key features include frequent volitional voiding every 2 to 3 hours until the voiding pattern has been reestablished, increased water intake (1 L/day) in addition to all other fluids consumed, correction of constipation, and adequate perineal hygiene.[27] Referral to a pediatric urologist may be necessary. Children who exhibit persistent inability to relax their sphincters may require training that involves relaxation techniques reinforced with biofeedback. Pharmacologic treatment with anticholinergics may be necessary if uninhibited bladder contractions are shown with urodynamic studies.[27] Special attention must be paid to the management of constipation if anticholinergic agents are initiated because they will exaggerate the problem.

Antibiotic Prophylaxis

Although antibiotic prophylaxis commonly is recommended for children with recurrent UTIs,[83] only limited data support this position. In a review of the literature, Le Saux and colleagues[83] found sparse data of low quality to support the use of antibiotic prophylaxis in children with a normal urinary tract. A meta-analysis by Williams and colleagues[168] revealed five randomized controlled trials assessing the use of prophylactic therapy. Of these, only two trials with 71 children evaluated the effectiveness of long-term, low-dose antibiotics to prevent UTIs.[91,148] The authors concluded that well-designed, randomized, placebo-controlled trials still are required to evaluate this commonly used intervention.

Vesicoureteral Reflux

The clinical significance of VUR as a predisposing factor for UTIs in general or APN in particular and its contribution to the formation of renal scarring have been questioned more recently. VUR is thought to increase the risk for UTI by increasing postvoid residual and allowing less virulent strains of bacteria to ascend into the upper tract and infect the kidney.[72] As a corollary to the latter, the question also has been framed as to whether long-term antibiotic prophylaxis is effective in reducing reinfection, thereby preventing renal damage in patients with VUR.[31] The authors concluded that the role of VUR in UTIs needs to be redefined through well-designed, multicenter, prospective, randomized, controlled studies using state-of-the-art renal imaging techniques.

Epidemiology

The incidence of VUR in the general population is thought to be approximately 1 percent.[24] Children usually are tested for the possibility of VUR in one of two clinical situations—during the assessment of prenatally diagnosed hydronephrosis and in the evaluation of a UTI. Reflux is diagnosed in 10 to 20 percent of cases of prenatally identified hydronephrosis; it often is high grade and occurs more frequently in boys than in girls in this situation.[42,135] The incidence of reflux in girls evaluated after a first UTI is 25 to 40 percent.[26,159]

An increased incidence of VUR within families suggests a genetic mode of transmission.[68] Rates for prevalence of VUR in identical and fraternal twins were 80 percent and 35 percent, providing evidence that this trait is transmitted in an autosomal dominant fashion. Siblings of children identified to have VUR as part of an evaluation for UTI have a much greater chance of having reflux than the normal population.[4,114] The presence of VUR in these siblings is accompanied by silent renal damage.[16] In addition, a girl who has reflux has a 65 percent risk for having affected offspring.[24] Reflux is much more common among white than black children.

Natural History

The natural history of reflux is for spontaneous resolution to occur over time, with a longer period being necessary in more severe types of reflux. Other factors that may affect the rate of resolution include age at diagnosis, gender, unilaterality versus bilaterality, and whether there is dysfunctional voiding. Average figures for spontaneous resolution are 80 to 86 percent for grade II reflux and 40 to 46 percent for grade III reflux during a 5-year period.

In a report from Skoog and associates,[146] spontaneous resolution occurred within 1.65 years of diagnosis in patients with grade II reflux, but 1.97 years was required for resolution in patients with grade III reflux ($p < .04$). Ninety percent of patients with reflux grades between I and III who ultimately had resolution of reflux experienced this result within 5 years. The rate of resolution was 30 to 35 percent per year, although the duration of reflux was shorter for patients in whom the diagnosis was made before they reached 1 year of age compared with patients who were older at the time of diagnosis.[7]

In another study of the natural history of reflux, Schwab and coworkers[139] determined the resolution rate by patient for 179 girls and 35 boys with UTIs and diagnoses of primary VUR between 1981 and 1984. Reflux spontaneously resolved in 68 percent of patients during the study. Grades I to III reflux resolved at a rate of 13 percent per year for the first 5 years of follow-up and then at a rate of 3.5 percent per year during subsequent follow-up. Grades IV and V reflux resolved at a rate of 5

IV	16	55	21	49	.14

percent per year. Bilateral reflux resolved more slowly than unilateral reflux and more rapidly in boys than in girls. There is no specific age in adolescence at which one can assume reflux will not resolve. Leneghan and colleagues[79] reported cessation of reflux after 14 years of age in 27 percent of patients observed without surgical intervention.

Management

The optimal management of children with high grades of reflux (grades III to V) has been the subject of numerous retrospective and prospective studies.[65,163,164] Since 1970, two large prospective randomized trials, the Birmingham Reflux study[9-11] and the International Reflux Study in Children,[125] have been performed to compare medical therapy (antibiotic prophylaxis) with surgical therapy (reimplantation of ureters). The International Reflux Study in Children reported results from Europe and the United States. Because entry criteria were different, the results have been reported separately.

In Europe and the United States, the surgical management of VUR is neither superior nor inferior to medical treatment. In both groups, new scars were acquired during the 5-year follow-up period, some in patients who did not show scarring at the time of entry. In other children, scars present at entry worsened.[119] No detectable differences were found between study groups in either renal function or renal growth. The number of episodes of infection also was similar in both groups. The only exception was a greater frequency of episodes of febrile UTIs (presumed pyelonephritis) in children receiving medical therapy.

Wheeler and colleagues[166] conducted a systematic review of randomized trials of the effects of various interventions in patients with VUR on the development of subsequent UTI and renal parenchymal injury. The aim was to evaluate whether any intervention for reflux (surgical) is better than nonsurgical treatment. Eight trials involving 859 evaluable children were reviewed. Seven trials compared antimicrobial agents alone with surgery plus antimicrobial prophylaxis. The risk for a UTI developing by 1 or 2 and 5 years was not significantly different between surgical and medical groups, and the risk for renal scarring or progressive renal damage occurring was similar. The choice of treatment remains a value judgment governed by such local factors as preference of the parents, availability of skilled surgeons, availability of closely supervised medical treatment, and willingness to comply with prolonged periods of prophylaxis.

Does VUR predispose to pyelonephritis? Garin and associates[31] reviewed 10 studies of children with acute UTIs who underwent DMSA scanning and VCUG. Selection of patients in at least one of the studies was biased toward the association between reflux and APN because the VCUG often was performed after the DMSA scan was reported to be abnormal. Six of 10 studies showed statistically significant results indicating that the presence of reflux definitely was associated with the occurrence of APN; all 4 of the remaining studies showed a trend in the same direction. Kerem, in his review of imaging, endorsed the observation that children with high-grade VUR (grades IV and V) are four to six times more likely to develop scarring than those with low-grade reflux and 8 to 10 times as likely as those with no reflux.[72]

Antimicrobial Prophylaxis

Although the use of antimicrobial prophylaxis had become routine in the management of children with VUR, substantial controversy currently surrounds this approach, and an increasing amount of literature challenges its benefit. In 2003, a Cochrane Review of the effectiveness of long-term antibiotics for preventing recurrent UTIs in children indicated that most studies published before this date were poorly designed without proper blinding.[169] Six recent randomized clinical trials have been performed to evaluate the effectiveness of antimicrobial prophylaxis in patients with VUR.* To provide comparable data from these six trials, authors of the 2011 American Academy of Pediatrics Clinical Practice Guideline for UTIs contacted the respective researchers and requested raw data from their studies. This allowed creation of a data set for 1091 infants, 2 to 24 months of age, according to grade of VUR. Table 39-6 and Figure 39-7 show that there are no significant differences in the rate of recurrences of febrile UTI/APN in young infants, with or without antimicrobial prophylaxis, according to the grade of VUR.[3]

Accepting for the moment that prophylaxis may be effective medical therapy that can be offered to children with severe degrees of reflux, the duration of prophylaxis also is an issue. VUR spontaneously remits in most cases during the first 3 to 5 years of life. Conventional wisdom

FIGURE 39-7 ■ **A,** Recurrences of febrile urinary tract infection (UTI)/pyelonephritis in 373 infants, ages 2 to 24 months, without vesicoureteral reflux (VUR), with and without antimicrobial prophylaxis (based on three studies; data provided by Drs. Craig, Garin, and Montini). **B,** Recurrences of febrile UTI/pyelonephritis in 72 infants, ages 2 to 24 months, with grade I VUR, with and without antimicrobial prophylaxis (based on four studies; data provided by Drs. Craig, Garin, Montini, and Roussey-Kesler). **C,** Recurrences of febrile UTI/pyelonephritis in 257 infants, ages 2 to 24 months, with grade II VUR, with and without antimicrobial prophylaxis (based on five studies; data provided by Drs. Craig, Garin, Montini, Pennesi, and Roussey-Kesler). **D,** Recurrences of febrile UTI/pyelonephritis in 285 infants, ages 2 to 24 months, with grade III VUR, with and without antimicrobial prophylaxis (based on six studies; data provided by Drs. Brandström, Craig, Garin, Montini, Pennesi, and Roussey-Kesler). **E,** Recurrences of febrile UTI/pyelonephritis in 104 infants, ages 2 to 24 months, with grade IV VUR, with and without antimicrobial prophylaxis (based on three studies; data provided by Drs. Brandström, Craig, and Pennesi). *CI,* confidence interval; *M-H,* Mantel-Haenszel test.

is that prophylaxis should be maintained until reflux ceases, either spontaneously or with surgical intervention. Greenfield and colleagues[39] suggested that two normal VCUGs performed 12 months apart are necessary before prophylactic antibiotics are discontinued. This recommendation is based on the observation that 27 percent of children exhibit VUR again after a single normal study.

Greenfield and colleagues[33] maintained that administration of prophylactic antibiotics should continue until reflux resolves, no matter what the age. They supported this position by noting that older children with reflux may have new scars evolve when they become infected. In contrast, other authors suggest that prophylaxis should be discontinued in older children, even if reflux persists.[2,7,21,153,171] The only two antimicrobial agents that are recommended for prophylaxis of the urinary tract are nitrofurantoin and trimethoprim-sulfamethoxazole. Each agent is used in half the usual therapeutic dose and given before bedtime. These two agents can often be used for months to years without the emergence of antibiotic resistance. However, some bacteria, such as *Pseudomonas*, are inherently resistant to both agents. In contrast, most other agents that are used for treatment of UTIs are not recommended for prophylaxis. Invariably, if agents such as amoxicillin, cephalexin, and second-generation and third-generation cephalosporins are used for prophylaxis, infection with resistant strains emerges within weeks.

Surgery

When antireflux surgery is undertaken, a variety of approaches are available, no one of which seems to be superior. In most cases, the surgical approach is intravesicular. Interest has been gaining in evaluation of an extravesicular approach to reimplantation of the ureters.[98] The advantage of extravesicular approaches seems to be a diminution of the intensity and frequency of bladder spasms and less requirement for postoperative analgesia. This technique is indicated primarily in unilateral VUR.[45] When experienced senior surgeons embark on reimplantation of ureters, the outcome usually is successful.[24] Generally, all surgical techniques have a high success rate of 92 to 98 percent.[45] Repeated operation for persistence or recurrence of reflux seldom is required. Rarely, when children younger than 2 years old undergo surgery, ureteral obstruction may result; its persistence mandates a second operation.[123]

A newer technique for the management of VUR is endoscopic injection therapy using a variety of materials. Developed as a minimally invasive approach to the treatment of VUR in 1984, dextranomer/hyaluronic acid copolymer (Deflux) has emerged as the favored bulking agent since its approval by the U.S. Food and Drug Administration.[44,95] A single injection of Deflux has been shown to correct VUR (decrease grade to 0 or I/V) in approximately 70 percent of patients, with long-term success rates of 80 to 95 percent for grades I and II VUR but significantly lower (43% to 73%) for grades III to IV VUR.[14,73] Furthermore, long-term outcome of the procedure has been assessed primarily for reduction in grade of VUR rather than prevention of infection or renal scarring. The bulking agent is injected beneath the ureteral orifice and effectively closes the distal ureter. The procedure is done in the outpatient setting and is associated with less pain and a quicker recovery compared with traditional reimplantation procedures.[95] The success rates are lower, however, than those of traditional therapy, and the results have questionable durability. Long-term prospective studies are necessary to evaluate endoscopic treatments critically.

PROGNOSIS

Generally, the short-term prognosis for previously normal children who experience an episode of UTI is excellent. In a large cohort of 306 children experiencing their first febrile episode of UTI, 40 percent were found to have reflux.[54] Only five (1.6%) of the children had grade IV reflux; none had grade V reflux. Most of the children with grades I, II, and III reflux can be expected to have spontaneous resolution of the process during the subsequent several years. Although many reports indicate that recurrent UTIs are common occurrences in children who have recovered from UTIs, recurrence during the first 6 months after recovery from the index episode of UTI was an infrequent event in this cohort of children. Recurrences in general, after a first UTI, vary according to the degree of VUR, as shown in Table 39-6.

Recurrence is seen most commonly in the early months after a symptomatic or asymptomatic UTI has occurred. Symptomatic reinfections (fever, pyuria, and positive urine culture) occurred in 7 children treated orally and in 11 children treated intravenously (for a total of 5.9% of 306 children) during the 6-month follow-up period.[54] Asymptomatic bacteriuria (positive urine culture in the absence of fever and pyuria) occurred in 1 child treated orally and in 2 children treated intravenously (1%). Renal

scarring occurred in 9.5 percent of all children; the average percentage of renal parenchymal involvement was 8.2 percent. In children who had an abnormal renal scintigram at the time of diagnosis, the frequency of scarring was 15.3 percent. None of the children with a normal renal scintigram at the time of diagnosis developed scars. This experience, reflecting an aggressive approach to the early diagnosis of UTI in infancy, is encouraging with regard to outcome.

Two recent studies have suggested that childhood UTIs are a rare cause of chronic kidney disease.[129,133] Using data from the literature, renal registries and medical records from a tertiary care hospital, it was concluded that in the absence of structural kidney abnormalities evident on imaging studies performed after the first UTI, the fraction of recurrent UTI as a main cause of chronic renal disease was small, ranging from 1/154 to 3/1000 or less.

When children with a diagnosis of UTI are found to have anomalies of the urinary tract, congenital dysplasias, or massive degrees of reflux, the prognosis is less optimistic. The most profound degrees of scarring are associated with advanced degrees of reflux. Reflux nephropathy is a major cause of severe hypertension in children and young adults. It occasionally progresses to chronic renal failure,[149] which accounts for approximately 25 percent of the children in the United Kingdom with end-stage renal failure requiring regular dialysis or transplantation.[84] Although surgical correction may relieve the reflux, the overall outcome for children with reflux who have undergone surgical correction has not been shown to be materially better than that for children who have been managed medically.[110,111,150]

Smellie and colleagues[147] undertook a randomized trial of medical management versus surgical correction in 53 children with bilateral severe VUR and bilateral nephropathy. The glomerular filtration rate of the children at enrollment was 20 mL/min/1.73 m^2 body surface area. Children with this degree of severity of renal impairment are rare; recruitment to this study took 5 years. No significant differences were observed in glomerular filtration rate, renal growth, or scarring during a 10-year follow-up period. The failure to find differences may be due to the small sample size and broad heterogeneity of the study group. Nonetheless, no convincing evidence that outcome for renal function is improved by surgical correction of VUR in children with bilateral disease exists.

PREVENTION

Primary prevention of UTI can be accomplished in infant boys by promoting the practice of circumcision. Whether this procedure can be justified simply to prevent UTIs in the context of social rituals is uncertain. Circumcision should be recommended, however, for selected groups of patients, including newborns with prenatal hydronephrosis who are found to have VUR in the neonatal period, boys with high grades of VUR, and boys in whom VUR is associated with unilateral renal agenesis or multicystic kidney.[15]

Other commonly recommended strategies to prevent UTI, such as the avoidance of bathing in tubs or swimming and the instruction in correct wiping techniques, are not accompanied by convincing evidence.[46] The relationship between constipation and UTI is well known. Effective treatment of constipation results in normalization of bladder function and cessation of UTIs.[90]

The role of prophylactic antibiotics for patients with VUR was discussed previously in the section on treatment. Prophylaxis has not been shown in large, prospective, placebo-controlled, randomized trials to reduce effectively the frequency of UTI and subsequent renal scarring either in patients with reflux or in patients who have experienced an episode of APN.* Although definite biologic plausibility to this likelihood exists, strong evidence is lacking.

An additional preventive strategy for UTI is immunization. A small pilot study was reported from Turkey.[105] Ten otherwise healthy girls aged 5 to 11 years old with recurrent UTIs were immunized with inactivated uropathogenic bacteria intramuscularly once a week for 3 consecutive weeks. A booster injection was given after 6 months. The frequency of infection was compared with that in a group of 10 age-matched girls with UTIs who were not immunized. Immunization therapy caused a significant reduction in the frequency of infection and an increase in the concentration of the secretory component of IgA in the urine. Other mucosa, such as vaginal and oral surfaces, are alternative targets for vaccine delivery.

A vaginal mucosal vaccine composed of a mixture of heat-killed bacteria from 10 human uropathic strains (6 *E. coli* and 4 other gram-negative enteric bacteria) was developed for women with recurrent UTIs.[157] Fifty-four women completed a double-blind, placebo-controlled, phase II trial. Time until reinfection was longest for women who received primary and booster immunization compared with women receiving a placebo. This strategy has potential for further development.

CHAPTER 40

Renal Abscess

Edmond T. Gonzales, Jr. • Sheldon L. Kaplan

Although acute pyelonephritis is a common infection in children, the primary development of a renal abscess or progression of pyelonephritis to a renal or perinephric abscess is an uncommon occurrence. In one study conducted over a 10-year period, 8 children with a renal abscess were found among 43,224 discharge diagnoses—approximately 1 case/5400 pediatric admissions.[5] Six of the eight children were 11 years or older. In a study from a children's hospital in Taiwan, 45 children were found to have a renal abscess over a 10-year period.[9] Although rare, renal abscesses have been reported in neonates.[10] Renal abscess may be a primary problem, that is, one that develops in a kidney without an antecedent infection or underlying anatomic abnormality, or it may occur secondarily in a patient with previously recognized acute pyelonephritis or in a child with congenital urologic abnormalities known to predispose to the development of pyelonephritis.

A primary renal abscess is thought to develop most often after an episode of bacteremia and frequently occurs in younger children. Hematogenous spread of bacteria to the kidney usually results in a cortical abscess.[5] The most common organisms involved in these abscesses are gram-positive cocci, primarily *Staphylococcus aureus* and less often *Streptococcus* spp. In some cases, a cutaneous infection might have been present before development of the renal abscess, and this infection is thought to be the primary source for the bacteremia.[16] Most children in whom a renal abscess develops hematogenously are normal hosts.[5,12,22,24] *Bartonella henselae* has been reported to cause microabscesses in the kidney.[17]

In older children and teenagers, tuberculous abscesses and caseous necrosis of the renal parenchyma also should be included in this primary classification. These infections tend to be indolent, although renal tuberculosis may be complicated by bacterial infection because of associated ureteral strictures and severe tuberculous cystitis. Pediatricians should become familiar with this "adult" malady because of the resurgence of tuberculosis and the generally older age group for which many pediatricians now provide care.

When a renal abscess occurs in association with a recognized urologic disorder, the organism responsible most often is a gram-negative bacillus or an enterococcus, bacteria usually seen in simple urinary tract infections and pyelonephritis.[19,21] Examples of urologic disorders that one might encounter with these infections include congenital and acquired obstructions (e.g., ureteropelvic

and ureterovesical obstruction, retrocaval ureter, ureteral stricture after surgical intervention), calculous disease (obstructing and nonobstructing), infundibular stenosis, and renal dysplasia with cystic changes. Abscesses that occur as a result of infection of the urinary tract generally are found in a corticomedullary location.[5]

Anaerobic organisms also have been implicated as a cause of renal abscess. They often are present simultaneously with the more usual aerobic bacteria, but they can cause infections and abscesses alone. These anaerobic renal infections develop most commonly in association with infections complicating bowel injury or surgery, renal transplantation, malignancy, and orodental infections.[4] The genus of the anaerobic organism may provide a clue to its source. *Bacteroides fragilis* is likely to arise from an intra-abdominal source, whereas an oral site is more common for *Prevotella oralis*.[4]

Children with human immunodeficiency virus infection seem to have an increased risk for development of renal abscesses from the more common traditional organisms[3] and from unusual opportunistic fungal organisms, especially *Aspergillus*.[14] As expected, these children also tend to have a more fulminant course that often requires extensive surgical intervention and drainage.

The presence of a renal abscess implies the destruction and liquefaction of tissue in a confined space. Two other infectious disorders of the kidney, xanthogranulomatous pyelonephritis and acute lobar nephropathy (acute focal bacterial nephritis), frequently are included in this general category, although technically, true abscesses do not always develop in these disorders. Acute lobar nephropathy may progress to renal abscess, however, if not treated appropriately.

Xanthogranulomatous pyelonephritis describes a more chronic form of severe renal parenchymal destruction that often is associated with chronic stone disease. The process may involve the whole kidney or may be focal. In children, the focal form occurs more commonly. The pathognomonic histologic finding is an accumulation of lipid-laden macrophages that coalesce into discrete yellow nodules. Small abscess cavities often are studded throughout the kidney. The organism most frequently recovered from the kidney is *Proteus*, and urinary calculi are common findings. Although these patients often have acute symptoms, the symptoms frequently are superimposed on more chronic manifestations, such as weight loss, failure to thrive, and anemia. Treatment is complete or partial nephrectomy because the renal destruction generally is severe.[23]

Acute lobar nephropathy describes a focal area of intense edema at the site of infection in acute pyelonephritis.[2] It usually is recognized as a mass effect on an initial screening renal ultrasonogram. Severe nephromegaly (renal length >3 standard deviations above the mean for age) is another finding on renal ultrasound suggestive of acute lobar nephropathy.[8] Computed tomography (CT) of the kidney shows poor uptake in the involved segment, but no well-defined liquefaction (Fig. 40-1). Whether this edema is just an exaggerated response to infection or represents a change before an abscess is unknown. Klar and colleagues[13] described 13 children, 4 months to 8 years of age, with acute lobar nephropathy in a prospective study during a 4-year period. Bacteremia was documented in only 1 child. Evolution to abscess formation occurred in 4 (31%). In another prospective study, Cheng and associates[6] found bacteremia occurred in 4 of 80 children (5%) with acute lobar nephropathy. In further studies these investigators noted that patients with acute lobar nephronia who had CT findings with heterogeneously decreased nephrographic density after contrast enhancement were more likely to develop a renal abscess than those with a homogenous decrease in density.[7] These lesions generally heal satisfactorily with administration of antibiotics alone.

CLINICAL FINDINGS

Children with acute renal abscess are febrile and have localized pain in the costovertebral location. Prolonged fever is a common finding, especially in older children. Most patients are febrile for longer than 7 days before the diagnosis is established. The initial findings generally do not differentiate, however, between acute pyelonephritis with and without an abscess. If the abscess has spread into the perinephric region, it may be possible to recognize psoas muscle irritation in the patient—that is, the patient is more comfortable with the ipsilateral leg in a position of flexion and experiences pain with full extension. A large abscess may be palpable as a flank mass.

Findings on urinalysis can be confusing. With a primary (hematogenous) abscess, the urine may be deceptively benign, and culture generally is negative.[16] Blood cultures may be positive, depending on the duration of the illness when blood is obtained for culture. Abscesses associated with underlying urologic disorders can be expected to contain organisms and pyuria. Generally, severe leukocytosis is present. The erythrocyte sedimentation rate typically is elevated; the same probably is true for C-reactive protein.[24] All of these findings are nonspecific, however, and often further studies are needed to establish the diagnosis. If a more indolent process is encountered, consider performing appropriate staining and cultures for tuberculosis should be considered.

DIAGNOSTIC EVALUATION

All children admitted to the hospital with a febrile urinary tract infection should undergo renal ultrasonography as soon as is reasonable after admission.[18] The findings on this initial study can have a significant effect on the choice of therapeutic options. If both kidneys are normal and unobstructed, organism-specific therapy is satisfactory in most patients. If significant obstruction or stones are present, antibiotic therapy may not be as effective, and interventional drainage may become necessary if the response to antibiotics is inadequate. At the time of this initial screening study, findings may suggest the presence of a renal abscess. Such findings include a mass effect within the margins of the kidney, along with a thickened wall and material of varying sonographic density within the mass (Fig. 40-2). Similar findings can be seen in

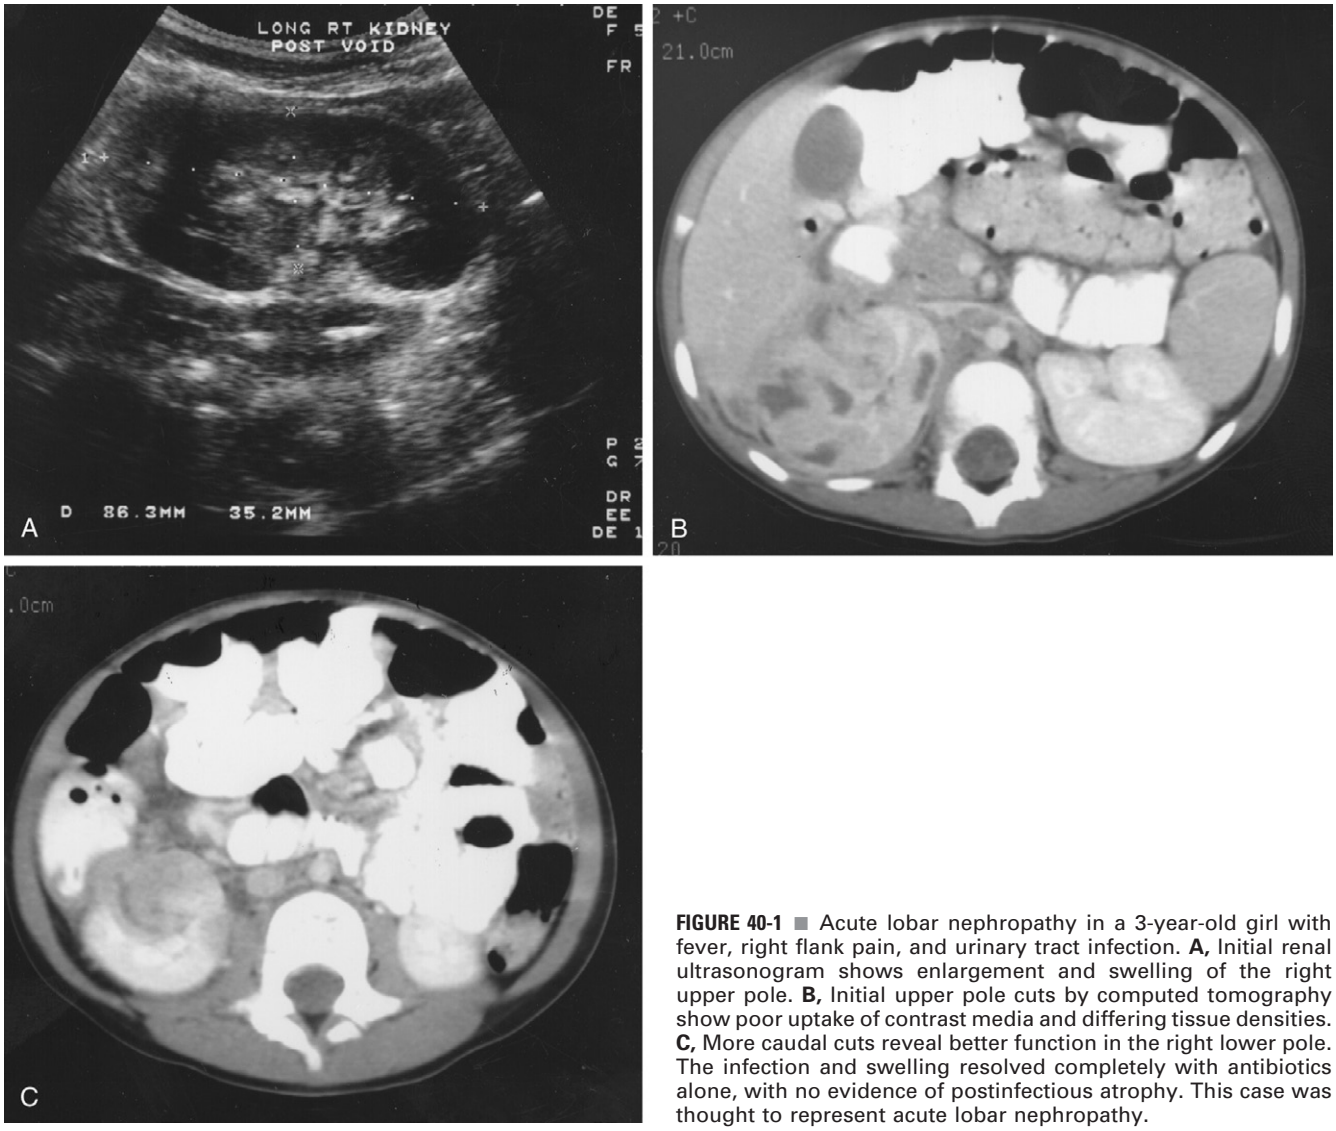

FIGURE 40-1 ■ Acute lobar nephropathy in a 3-year-old girl with fever, right flank pain, and urinary tract infection. **A,** Initial renal ultrasonogram shows enlargement and swelling of the right upper pole. **B,** Initial upper pole cuts by computed tomography show poor uptake of contrast media and differing tissue densities. **C,** More caudal cuts reveal better function in the right lower pole. The infection and swelling resolved completely with antibiotics alone, with no evidence of postinfectious atrophy. This case was thought to represent acute lobar nephropathy.

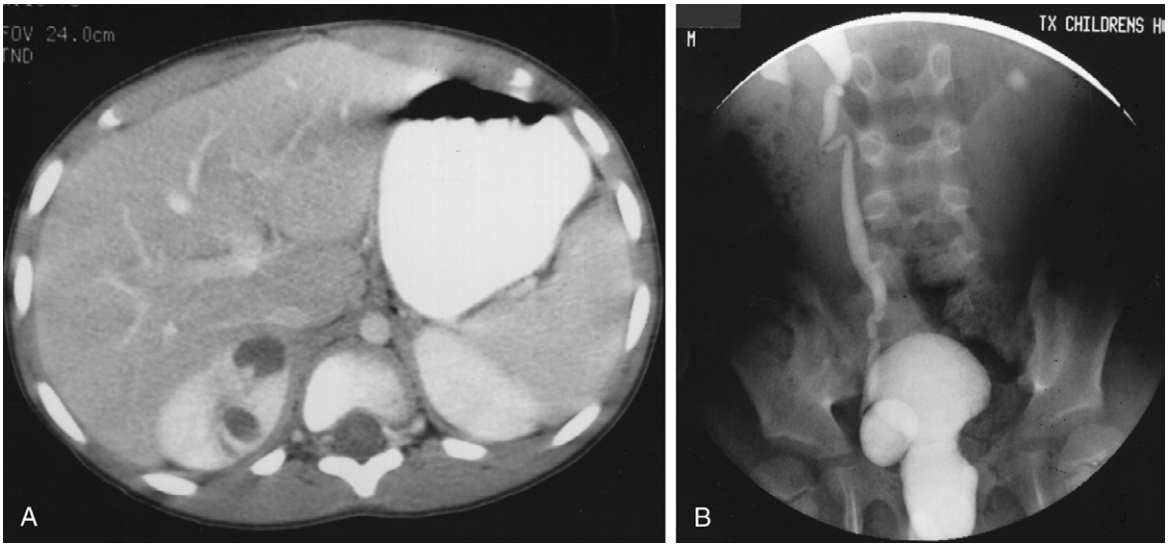

FIGURE 40-2 ■ Renal abscess (secondary) in a 6-month-old boy with urinary tract infection. A screening renal ultrasonogram showed a small mass in the right kidney. **A,** Computed tomography shows two clearly defined cystic areas consistent with small parenchymal abscesses. Treatment consisted of intravenous antibiotics only. **B,** Voiding cystogram revealed the presence of vesicoureteral reflux.

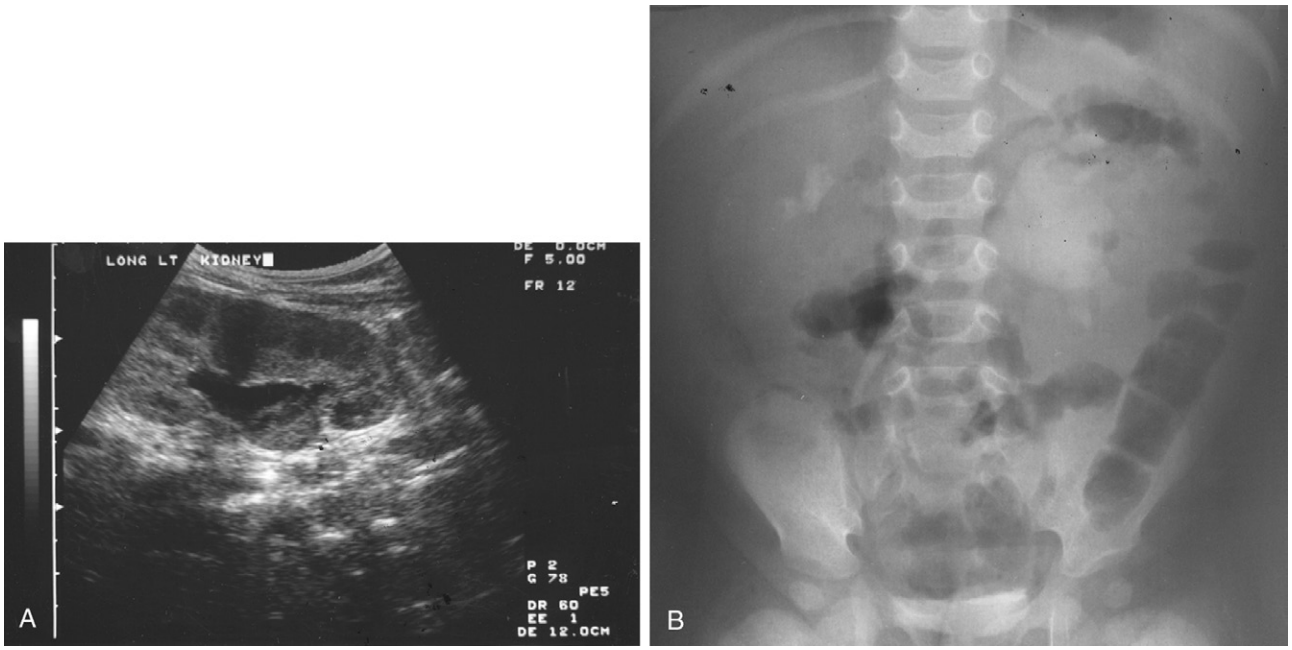

FIGURE 40-3 ■ Pyonephrosis associated with ureteropelvic junction obstruction in a 3-month-old boy with fever, left abdominal and flank tenderness, and urinary tract infection. **A,** Renal ultrasonogram shows a medially placed cystic mass with layered fluids of different density consistent with purulent material. The position of the mass is most consistent with the renal pelvis. **B,** Intravenous pyelogram confirms ureteropelvic junction obstruction. This infant was treated initially with percutaneous nephrostomy drainage in addition to appropriate antibiotics.

infections accompanied by severe ureteropelvic junction obstruction or infundibular stenosis with isolated calyceal dilation, in which case purulent material within the dilated collecting system layers out and can mimic a renal abscess (Figs. 40-3 and 40-4). Nephromegaly on ultrasonography also has been found to be a clue to recognizing a renal abscess with subsequent CT imaging studies.[9]

When the diagnosis of an abscess is suspected on ultrasonography, performing CT of the involved kidney is in order.[11] CT more clearly defines the margins of the abscess, assesses whether loss of function is significant, and can screen the remainder of the kidney for small satellite abscesses.[20] If loss of function in the affected kidney seems to be significant, a dimercaptosuccinic acid renal scan should be done because it is an even more sensitive test to quantitate overall renal function. If CT suggests the diagnosis, percutaneous aspiration can confirm clearly whether an abscess is present, without having to perform additional studies, and, at the same time, provide material for culture.

If a child with a urinary tract infection and a previously normal result on renal ultrasonogram is taking culture-specific antibiotics and a new fever subsequently develops, ultrasonography should be repeated. A previously small, unrecognized abscess may have been treated inadequately and now may be more apparent.

Occasionally, imaging studies cannot distinguish between a renal abscess and severe acute lobar nephropathy. The latter condition also may show tissues of differing density by ultrasonography or CT. In these situations, ultrasonography-guided or CT-guided percutaneous aspiration of the lesion may be necessary to determine whether purulent material can be obtained.

THERAPEUTIC CONSIDERATIONS

When the diagnosis of an abscess is confirmed, the choice of therapeutic options is dictated by several factors, including the overall status of the patient, the size and number of abscesses, whether the abscess appears to be unilocular or septate, associated uropathies, and the extent of renal function in the involved kidney. Included in these considerations is some insight into the responsible organism. If it is a solitary abscess in a child with unimpressive urinalysis findings and an otherwise normal kidney, one should suspect a staphylococcal abscess, which can be confirmed by percutaneous aspiration, Gram stain, and culture. If bacteremia caused by *S. aureus* possibly was nosocomial in origin, or if methicillin-resistant *Staphylococcus aureus* isolates are found commonly in the community, antibiotics such as vancomycin or clindamycin should be included in the initial empirical regimen.

Subsequent therapy is based on the antibiotic susceptibility pattern of the organism isolated. If urinalysis reveals an obvious infection, one can assume that the urine culture reflects the organism responsible for the abscess. In this situation, empirical therapy is directed against gram-negative enteric organisms. Cefotaxime, ceftriaxone, or ceftazidime plus an aminoglycoside would be suggested. The only caution is if the abscess is complicated by significant stone disease. In this situation, more than one organism may be in the urinary tract, and urine culture alone may be misleading. Percutaneous aspiration can identify accurately the organism responsible for the abscess. The optimal duration of antibiotic therapy for treatment of a renal abscess is not established,

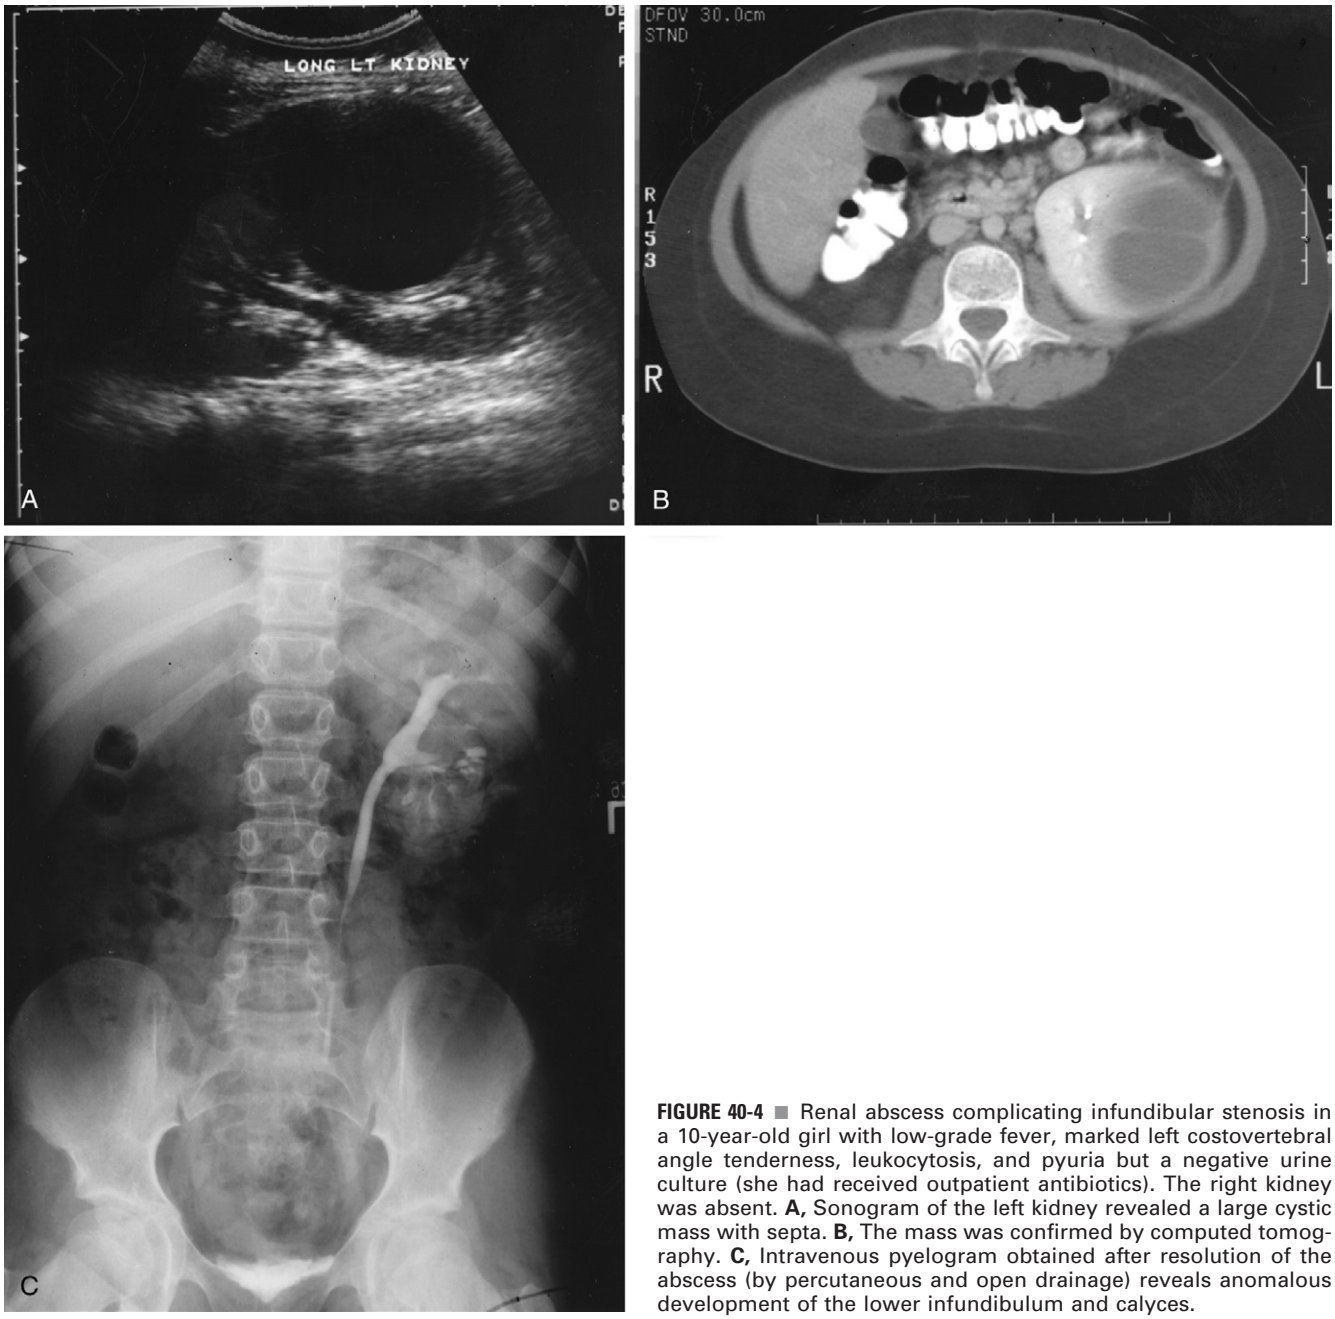

FIGURE 40-4 ■ Renal abscess complicating infundibular stenosis in a 10-year-old girl with low-grade fever, marked left costovertebral angle tenderness, leukocytosis, and pyuria but a negative urine culture (she had received outpatient antibiotics). The right kidney was absent. **A,** Sonogram of the left kidney revealed a large cystic mass with septa. **B,** The mass was confirmed by computed tomography. **C,** Intravenous pyelogram obtained after resolution of the abscess (by percutaneous and open drainage) reveals anomalous development of the lower infundibulum and calyces.

but 3 weeks of treatment is superior to 2 weeks for acute lobar nephropathy.[6]

Renal abscesses traditionally have been managed by open surgical drainage. With the introduction of safe percutaneous access, particularly when used with ultrasonography or CT guidance, single, unilocular lesions now can be managed effectively with percutaneous placement of an indwelling catheter that allows not only for primary drainage but also for irrigation of the cavity with appropriate antibiotic solutions.[1,13] Small renal abscesses have been treated successfully with antibiotics alone.[15,22] If the child does not improve with medical therapy alone, some type of drainage procedure is indicated. When function is insufficient to justify renal salvage and ultimate nephrectomy is planned, a short course of specific antibiotics and percutaneous drainage is initiated, if the abscess is large, to decrease inflammation in the perinephric tissues and to reduce the possibility of causing bacteremia at the time of surgery.

When required, surgical repair of associated congenital anomalies of the urinary tract generally is performed at a separate session after the abscess has resolved. Reconstructive surgery in the presence of active infection significantly increases the risk for development of surgical complications and the possibility that additional surgical procedures might be required.

CONCLUSION

Treatment of renal abscess today is multifaceted, and each case must be individualized. In addition to culture-specific antibiotics, treatment may include observation only, percutaneous drainage, or open surgical drainage. Diagnostic evaluation, including renal ultrasonography, CT, and percutaneous aspiration, generally can confirm that an abscess is present and assist in the decision regarding therapeutic options.

CHAPTER 41

Prostatitis

Sheldon L. Kaplan

Prostatitis, a major source of chronic infection and symptoms in men, occurs rarely in prepubertal children. Although prostatitis may develop in postpubertal teenagers, even in this age group the diagnosis is recognized infrequently. The disorder commonly termed *prostatitis* generally is divided into four separate clinical problems based on the National Institutes of Health Classification of prostatitis: acute bacterial prostatitis, chronic bacterial prostatitis, chronic prostatitis and chronic pelvic pain syndrome, and asymptomatic inflammatory prostatitis.[9] This chapter will focus on acute or chronic bacterial prostatitis.

Acute prostatitis is a severe infection generally associated with significant toxicity (high fever, systemic symptoms such as malaise, chills, nausea, and vomiting).[19] Marked urinary symptoms, such as frequency, suprapubic pain, dysuria, hematuria, and urinary retention, may be present. On rectal examination, the prostate is enlarged, boggy (edematous), and exquisitely tender. The urine usually is infected. Care must be taken when performing the rectal examination or when inserting a transurethral catheter because bacteremia can result. The white blood cell count and inflammatory markers are usually elevated. Urinalysis is abnormal and urine culture is positive in the majority of cases. Bacteremia has been reported in up to 20 percent of patients and blood cultures may be positive when urine cultures are negative.[5]

The organism responsible usually is one of the gram-negative pathogens that commonly causes urinary tract infection (UTI). *Escherichia coli* is most commonly isolated, but other pathogens include *Proteus mirabilis*, *Pseudomonas aeruginosa*, and *Klebsiella* and *Enterococcus* spp., among others.[3] *Neisseria gonorrhea* is a consideration in sexually active males. Community-acquired methicillin-resistant *Staphylococcus aureus* has been isolated, rarely, from patients with a prostatic abscess.[18] The virulence factors of *E. coli* strains recovered from men with acute prostatitis and women with UTIs, such as adhesins and cytotoxins, were similar in one study.[15] Johnson and colleagues[7] found, however, that prostatitis *E. coli* isolates differed significantly from *E. coli* associated with cystitis or pyelonephritis by having a higher prevalence of the genes encoding P fimbriae structural subunits, P fimbriae assembly, fimbriae tip pilins, hemolysin, and cytotoxic necrotizing factor and a lower prevalence of the gene encoding invasion of brain endothelium virulence factor. In a study of *E. coli*, isolates from 18 previously healthy young men with acute bacterial prostatitis, Krieger and colleagues[10] reported that most isolates fell within the family of considered extraintestinal pathogenic *E. coli* (ExPEC) and carried a median of 12.5 virulence genes, characteristic of ExPEC gene clusters. Rarely, *Trichomonas vaginalis* can cause prostatitis.

If the patient is not systemically ill, in adults a quinolone, such as ciprofloxacin or levofloxacin, or

trimethoprim-sulfamethoxazole is generally recommended because these agents have been more carefully studied for this indication than oral cephalosporins.[12] These same agents also are reasonable for male adolescents. Modification of antibiotic therapy is based on the organism isolated and its antibiotic susceptibilities. The duration of treatment is generally 14 to 28 days. If the patient is more seriously ill, parenteral therapy is recommended. Empirical treatment generally begins with administration of broad-spectrum β-lactam agents, such as cefotaxime or piperacillin-tazobactam, possibly combined with an aminoglycoside, that are effective against gram-negative enteric organisms, pending the availability of culture-proven sensitivity results and a satisfactory clinical response. Once the patient has clearly improved and is stable, therapy can be completed with an oral agent such as a fluoroquinolone or trimethoprim-sulfamethoxazole based on susceptibility results.

Chronic bacterial prostatitis is a more indolent infection associated with intermittent UTI, bladder irritative symptoms, and perineal discomfort. Recurrent urethritis or epididymitis may be present. Ejaculation may be painful. Expressed prostatic secretions usually show an increase in the white blood cell count. Common organisms associated with chronic bacterial prostatitis are similar to those causing acute bacterial prostatitis, including *Klebsiella* spp., *E. coli*, *P. mirabilis*, *P. aeruginosa*, and *Enterococcus faecalis*.[19] *E. coli* isolates associated with chronic prostatitis possess urovirulence profiles similar to those of strains from women with acute uncomplicated pyelonephritis.[1]

The diagnosis of chronic bacterial prostatitis is related partly to detecting inflammation in expressed prostatic secretions. More precise methods of determining inflammatory parameters, such as counting the white blood cells per cubic millimeter with a hemocytometer, have been proposed.[16] In a large cohort study, the severity of symptoms in men with chronic prostatitis did not correlate with leukocyte or bacterial counts, however.[20]

Chronic bacterial prostatitis accounts for only a small fraction of men with chronic prostatitis syndromes. The cause of nonbacterial chronic prostatitis and chronic pelvic pain syndrome remains enigmatic. Prostatic secretions do not show a common organism consistently, and UTI does not recur. Culture of prostatic secretions is notoriously unreliable, because of the means by which this material is collected; these secretions are contaminated easily as they pass through the urethra.[14] A specific causal relationship in nonbacterial prostatitis has not been found for either *Ureaplasma urealyticum* or *Chlamydia trachomatis*, two organisms commonly implicated in urethritis.[21] Molecular studies using polymerase chain reaction have shown DNA evidence of the presence of bacteria despite negative cultures for the typical bacteria associated with prostatitis. Using these new techniques may lead to greater understanding of the role of infection in the pathogenesis of prostatitis.

Treatment of chronic bacterial prostatitis is frustrating because few patients truly are cured, and relapse occurs commonly after discontinuation of antibiotic therapy. Several studies have confirmed satisfactory concentrations of most common antibiotics in prostatic tissues,[6,8,11,13] but no study has provided a convincing explanation for the high treatment failure rate. Levofloxacin and other fluoroquinolones penetrate well into seminal and prostatic fluids and reach concentrations equivalent to corresponding plasma levels.[4] Researchers have postulated that antibiotic concentrations may be inadequate within the acini of the prostatic glands and their secretions, but this theory has not been proved.[17] Typically, fluoroquinolones for 4 to 6 weeks of administration are the agents of choice for treating chronic bacterial prostatitis.[12]

In the older age group still seen in a pediatric practice, symptoms similar to those of the chronic form of prostatitis also might occur with urethritis. As noted earlier, *Chlamydia* and *Ureaplasma* spp. commonly are found in the urethral discharge in these patients[2] and are thought to be responsible for these specific symptoms. These organisms also have been implicated as a cause of epididymitis in young men. The organisms are transmitted sexually and are treated effectively with a tetracycline (minocycline or doxycycline) or a macrolide (erythromycin or azithromycin).[22] To prescribe these drugs empirically for sexually active young adults with lower tract irritative symptoms and clinical findings consistent with urethritis while awaiting culture results seems reasonable.

Nonspecific urethritis is the term commonly used for the infection in men with irritative voiding symptoms and a clear mucoid discharge and in whom culture of the discharge reveals a mixture of common perineal and gram-negative organisms but without a predominant organism thought to be responsible for the infection. Some of these patients likely have undiagnosed *Chlamydia* or *Ureaplasma* infection. Although specific treatment is empirical, a tetracycline or macrolide seems to be a prudent first choice in most cases. Finally, one must not overlook the possibility of gonococcal urethritis.

In males, ectopic ureters can drain into the prostatic urethra or the seminal vesicle. With this anomaly, the ipsilateral renal parenchyma generally is dysplastic, the ureter is highly dilated, and the seminal vesicle may be distended markedly and form a large cystlike structure behind the prostate, the bladder neck, and the trigone. If this anomaly becomes infected, pain in the perineum and on rectal examination generally is significant. Occasionally, frankly purulent material is passed at the urethral meatus or expressed from the urethra after rectal examination.

In most cases, the kidney drained by the ectopic ureter is highly dysplastic and shows little or no function. Ultimate management usually consists of nephroureterectomy (ureteroneocystostomy if the kidney works) and, if the seminal vesicle is unusually large, partial excision and decompression of the seminal vesicle. Although these abnormalities are congenital and easily recognized by fetal ultrasonography, they can occur at almost any age if not identified before birth. Unless a palpable flank or lower abdominal mass is felt, infection usually is the initial symptom. Despite the severe degree of abnormality and ureteral and seminal vesicle dilation, the development of infection can be delayed well into the adult years. Infrequently, distortion at the bladder neck can result in obstruction to urinary flow.

SUMMARY

Prostatitis as it is seen and described in adults is a rare event in pediatric patients. When it does occur, it affects pubertal adolescents. Even in these patients, distinguishing true prostatitis from simple urethritis may be difficult.

Appropriate evaluation of an adolescent boy with a lower tract urinary infection generally begins with renal ultrasonography. Special attention should be directed to the region of the bladder and prostate. With this imaging modality, the presence and normalcy of both kidneys, the degree of thickening of the bladder wall, the ability of the bladder to empty, and whether any cystic masses are located behind the bladder or prostate can be assessed. Any obvious abnormality justifies obtaining a voiding cystourethrogram. A thickened detrusor or recurrence of infection suggests the possibility of urethral obstruction. Although properly performed voiding cystourethrography does image the entire urethra, other diagnostic tests might include retrograde urethrography or determination of the urinary flow rate, especially if a urethral stricture is suspected. Performing cystoscopy usually is unnecessary if all imaging study results are normal, although cystoscopy may be used to confirm, and sometimes manage, obvious urethral obstruction.

CHAPTER 42

Genital Infections

Mariam R. Chacko • Mary Allen Staat • Charles R. Woods, Jr

This chapter reviews female genital tract infections in the pediatric and adolescent age groups. An initial review of normal vaginal microenvironment in the prepubertal, pubertal, and postpubertal period is followed by a section on lower genital tract infection in the prepubertal, pubertal and postpubertal period. This section addresses infections of the external genital area, including vulvovaginitis; infections of the clitoris, urethra, and Bartholin ducts and glands; vulvovaginal lesions; ulcerative and granulomatous disorders; and infections of the cervix. Upper genital tract infections are rare in the prepubertal age group; thus, discussion of pelvic inflammatory disease (PID), tubo-ovarian abscess, and oophoritis, which follows, is predominantly addressed for the postpubertal period. Additional information on the microbes and the specific detailed treatment recommendations can be found in the respective chapters on each pathogen. Genital infections associated with pregnancy are not addressed in this chapter.

Supplemental information concerning the principles of gynecologic infections in children and adolescents can be found in referenced sources.[8,59,102,104]

GENERAL APPROACH TO EVALUATION OF PREPUBERTAL CHILD

When genital tract symptoms are present in young girls, the history should include information about the manner and circumstances surrounding the onset of the complaint, the characteristics of any discharge, the duration of symptoms, whether the problem is recurrent, and the nature of any recent treatments or medications. Information should be elicited regarding the use of bubble baths,

enuresis, history of atopic dermatitis or allergies, anal pruritus (associated with pinworm infection), recent respiratory or skin infections in family members, and hygienic practices. The possibility that the child may have had or has a systemic disorder affecting the genitalia should be explored.

Sexual abuse also must be considered when a child has a genital infection, regardless of the nature of the infection or the socioeconomic status of the family. This concern is particularly relevant when the child has a sexually transmissible disease. Sexual abuse does not require penile penetration of the vagina. The history of vaginal or penile discharge in other family members should be ascertained. Behavioral changes, nightmares, fears, abdominal pain, headaches, and enuresis can be indicators of abuse or other psychosocial stressors. The possibility of nonsexual transmission of these diseases often is raised, particularly when a preliminary investigation cannot elicit a history of sexual abuse. The rate of eliciting evidence of sexual abuse in prepubertal children can be 67 percent, however, in children with sexually transmitted infections (STIs).[12] Based on a review of the literature, common STIs in premenarcheal children and their potential mode of transmission are also summarized.

A general physical examination should precede assessment of the genital tract. The gynecologic examination begins with abdominal inspection and palpation followed by external examination of the perineum and genitalia, including the vulva, urethral meatus, clitoris, hymen, and anus. The examination should be done with the child in the supine, frog-leg position. The labia can be retracted gently to visualize the anterior of the vagina. Speculum and bimanual examinations generally are inappropriate in prepubertal children.[57,160] Note should be made of structural abnormalities, inflammation, sores and ulcerations, and excoriations. If complaints consist only of vulvitis, and findings on external examination are limited to a scanty mucoid discharge and an erythematous introitus, further examination generally is unnecessary.[58]

If the vaginal discharge is purulent, persistent, or recurrent, a thorough gynecologic assessment is warranted. Visualization of the vagina and cervix without instrumentation is possible with the child in the prone knee-chest position.[57] This method is useful in children older than 2 years. In this position, with labial traction, the vaginal muscles relax and stretch the hymenal membrane open. An otoscope head or a magnifying lens with a good wall light is used to visualize the cervix. Because the vagina of a prepubertal child is short, a foreign body or a lesion may be seen.[57]

A rectal examination may be important when persistent discharge, bleeding, or pelvic or abdominal pain is present. The rectal examination may help express discharge from the vagina that previously was not recognized and can permit palpation of hard foreign bodies or abnormal masses.

Visualization with instrumentation (vaginoscopy) is required in some situations. General anesthesia may be required for girls who are small or unable to cooperate or who may experience significant anxiety or discomfort during the procedure. Conscious sedation for the procedure may be an option in some situations. When a purulent, persistent, or recurrent vaginal discharge is present, samples should be obtained for culture and Gram stain. Wet mount preparations may be useful if fungal infection (potassium hydroxide preparations) or pinworms are suspected. Saline wet mount may be indicated for trichomoniasis if sexual abuse is suspected. Urinalysis with microscopic examination should be performed. A complete blood cell count may be useful when pyogenic infection is suspected or bleeding has occurred.

When cultures are indicated, separate vulvar and vaginal specimens may be necessary. The type and duration of discharge and considerations of potential sexual abuse influence this decision. Vulvar specimens alone may be appropriate when etiologies such as group A streptococci are suspected. Exudates emanating from the vagina in prepubertal girls also are adequate specimens for evaluation for gonorrhea, such that vaginal swabs or aspirates are not required. Further information on types of specimens required for specific sexually transmitted infections such as gonorrhea or *Chlamydia trachomatis* is provided in Chapters 89 (gonorrhea) and 193 (*C. trachomatis*).

Options for obtaining vaginal specimens in young girls, when needed, include use of (1) a nasopharyngeal Dacron swab moistened in nonbactericidal saline, inserted carefully through the hymenal opening; (2) a catheter-within-a-catheter technique (Fig. 42-1)[160]; or (3) a sterile newborn suction catheter, with insertion 2 to 3 cm into the vagina.[202] For the catheter-within-a-catheter technique, the distal 4 inches of a soft, size 12 bladder catheter and the proximal 4 inches of butterfly needle intravenous tubing are excised from their parent devices by sterile technique. The catheter-within-a-catheter is inserted into the vagina, and fluid is flushed in and out of the upper part of the vagina several times before final aspiration into the syringe and removal of the device.

NORMAL VAGINAL FLORA

The lower female genital tract is colonized by nonpathogenic bacteria from birth. Throughout life, this colonization is dynamic and complex. A wide range of aerobic and

anaerobic species have been cultured from asymptomatic girls. The results of several modern series are summarized in Table 42-1. The vagina and its microbial flora form an ecosystem that changes over time from infancy to childhood to adolescence and adulthood.[99] The major forces that influence these changes are fluctuations in estrogen levels and the advent of sexual activity. Hygienic practices and medications, including oral contraceptives and antimicrobial agents, also affect the complex interactions among the various flora present in the vagina in terms of persistence, predominance, and overgrowth.

Most girls harbor several organisms in the vagina at any given time. Younger adolescents have a greater prevalence of anaerobic bacteria than do women. From puberty, aerobic colonization increases with age, onset of sexual activity, and parity.[127] Vaginal specimens obtained for culture during anesthesia for elective surgery from 19 healthy girls aged 3 months to 5.7 years old yielded a mean of 12 bacterial species.[98] Anaerobes predominated, with a mean of 8.7 species versus 3.4 aerobic species. In a series of 25 asymptomatic girls aged 2 months to 15 years, a mean of 8.7 different species (approximately four aerobes and five anaerobes) per vaginal specimen were detected.[87] Another series of adolescents and young adults aged 13 to 21 years in which only aerobic flora were evaluated noted a mean of approximately three organisms in non–sexually active subjects versus six in sexually active patients.[186] This heterogeneity in vaginal microflora during childhood and adolescence is similar to that found in women.[126]

Gram-negative enteric bacteria and enterococci commonly are encountered in infants and toddlers before completion of toilet training, but less frequently thereafter.[87,98] In children, lactobacilli are present more often in girls younger than 2 years than in older prepubertal girls. Lactobacilli are the predominant flora in most girls by the end of adolescence and may play a protective role in limiting the overgrowth of other flora.[99] The vaginal flora of most healthy women is dominated by one or more *Lactobacillus* spp., but a substantial minority may harbor other predominant flora, including *Bifidobacterium*, *Gardnerella*, *Prevotella*, *Pseudomonas*, or *Streptococcus*, in the absence of lactobacilli.[105]

The increasing presence of yeast and *Gardnerella vaginalis* from puberty to adulthood, although much less common in all ages, parallels that of lactobacilli.[87] *Mycoplasma hominis* and *Ureaplasma urealyticum* are present more commonly in sexually active adolescents and in girls of any age who have been sexually abused than in non–sexually active girls. Genital mycoplasmas were found in 17 percent of one series of young girls who were not known to have undergone any sexual abuse.[90,186]

Microbes that usually behave as commensals sometimes are associated with vulvovaginitis. The difference between colonization and disease is at least partially a function of the magnitude of the replication and the quantity of a given bacterial species. For example, in women with bacterial vaginosis in which *G. vaginalis* is a predominant microbe, colony counts generally are greater than 10^7 colony-forming units/g of vaginal fluid. Asymptomatic colonization with *G. vaginalis* usually is associated with colony counts of less than 10^5 colony-forming units/g of vaginal fluid.[127] Alteration in the vaginal microenvironment by factors such as poor hygiene, foreign bodies, or hormonal fluctuations results in loss of environmental constraints on bacterial replication and facilitates the overgrowth of one or more commensals.

LOWER GENITAL TRACT INFECTIONS

This section includes the following topics according to anatomic areas: vulvovaginitis; infections of the clitoris, urethra, and vulvar glands; genital lesions, ulcerations, and granulomatous infections and cervicitis. Each topic addresses the prepubertal and postpubertal aspects of infections where relevant.

Vulvovaginitis

Prepubertal

Infections and inflammation of the vulva and vagina account for 85 to 90 percent of all genital problems in prepubertal girls. These conditions are encountered most commonly in children 2 to 7 years old.[159,171] Infections of the vulva and vagina usually occur together and generally are considered one entity—vulvovaginitis. The various types of vulvovaginitis are differentiated by determining the presence or absence of specific microbial or other agents associated with the inflammation in a particular case.

Genital discharge does not always indicate infection or inflammation. Most female infants have a grayish white, mucoid discharge from the vagina during the newborn period. This discharge consists of desquamated vaginal mucosa and cervical epithelium that has undergone hypertrophy because of prenatal stimulation by placental and maternal hormones. Microscopic examination of the material reveals masses of large, superficial vaginal epithelial cells (Fig. 42-2). The condition may last for several weeks, is not pathogenic, and does not require treatment.

Similarly, a pubertal girl nearing menarche may develop a copious viscous, transparent secretion that exudes from the vagina. This normal state sometimes raises concern about possible vaginal infection. The vulvar and vaginal tissues appear thick and moist, a sign of increased estrogen stimulation, without erythema. Microscopic examination of the vaginal fluid reveals masses of estrogenized superficial vaginal epithelial cells and few leukocytes (Fig. 42-3).

Genital discharge and perineal or vulvar discomfort are the most common symptoms of vulvovaginitis.[59,159,192] The discomfort may range from minor pain or soreness to intense perineal burning or pruritus. Genital erythema is the most common sign in girls, and vulvovaginitis can be found in more than 80 percent of cases. Visible discharge is present in one third of cases.[159] Infections of the vulva and vagina are more likely to be accompanied by moderate or severe inflammation and prominent discharge than is nonspecific vulvovaginitis.[112] Infection can be present at times, however, with neither discomfort nor discharge.

The characteristics of the discharge frequently do not help identify a specific cause. At the onset of an infection, the discharge is often thick, purulent, and profuse. It may become scanty and seropurulent in later stages of infection.[58] Discharges that are odorless and bloody or serosanguineous may result from noninfectious conditions, such as vulvar irritation, trauma, precocious puberty, urethral prolapse, and tumor. Vulvovaginitis caused by *Shigella* or group A streptococci also can cause bleeding, as can an eroding foreign body. Foul-smelling discharge suggests a foreign body but also may result from a necrotic tumor. Urinary leakage from an ectopic ureter opening into the genital tract may mimic a vaginal discharge. Specific diagnoses are made more often when symptoms have been present for less than 1 month.[214]

In a series of 80 prepubertal and pubertal girls aged 2 to 12 years old with vulvovaginitis and no suspicion of sexual abuse, probable bacterial pathogens were found in cultures of 36 percent. Group A streptococci, *Staphylococcus aureus*, and *Haemophilus influenzae* (non–type b) were the most common isolates.[202] In another series of 74 girls, group A streptococci and *H. influenzae* were isolated in 47 percent and 12 percent. Most of these girls had

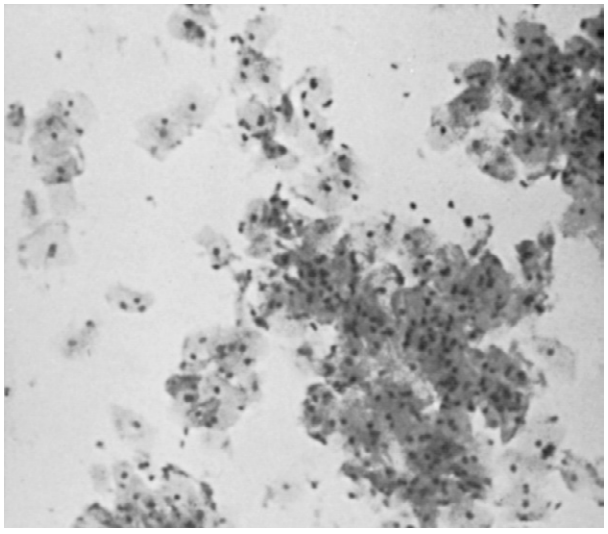

FIGURE 42-2 ■ Cytosmear from the vaginal discharge of a newborn.

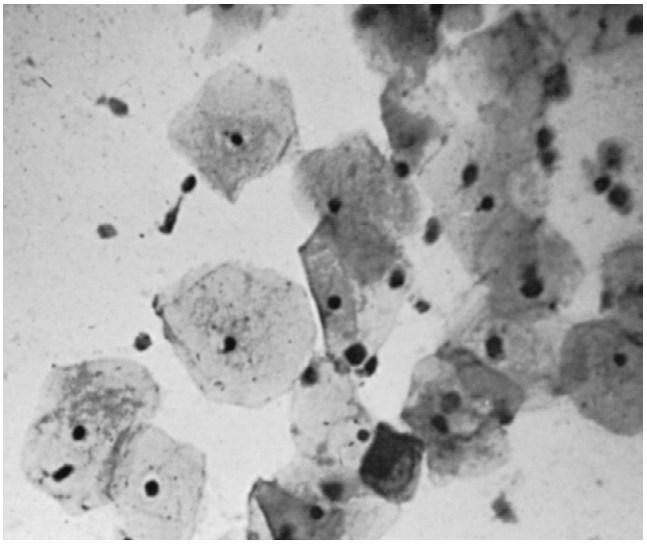

FIGURE 42-3 ■ Cytosmear from the vaginal secretion of a pubertal girl. Masses of epithelial cells and few bacteria or leukocytes attest.

symptoms for 7 days or less at the time treatment was sought.[44] These bacteria, especially group A streptococci, causing vulvovaginitis may lead to more severe symptoms that result in care being sought soon after onset, whereas pathogenic bacteria generally are less likely to be found when girls initially are examined after several weeks of symptoms.

Postpubertal

Infections of the pubertal and postpubertal vulva and vagina produce a variety of overlapping symptoms, including vulvar pruritus, dysuria, and increased or altered vaginal discharge and spotting.[226] As a result, distinguishing among various lower genital tract infections based solely on symptoms is difficult. The history, physical examination, and laboratory tests play an important role in assisting the clinician in differentiating urethritis, vaginitis, and cervicitis.

Nonspecific Vulvovaginitis

Nonspecific vulvovaginitis is a frequently encountered condition in prepubertal girls and is addressed in this section. Nonspecific vaginitis in postpubertal females is now called bacterial vaginosis and is addressed in its respective section in this chapter.

Prepubertal. Nonspecific vulvovaginitis is responsible for 25 to 75 percent of cases of vulvovaginitis diagnosed in the prepubertal age group in referral centers.[214] In most cases, as noted in Table 42-2, identifiable secondary factors contribute to nonspecific vulvovaginitis. The presence of specific genital tract bacterial or viral pathogens excludes this diagnosis.

Poor hygiene with subsequent overgrowth of a mixed aerobic and anaerobic bacterial flora that are typically nonpathogenic on mucosal surfaces is the most common cause of premenarcheal vulvovaginitis.[156] Contact irritation and allergic reactions induced by soaps, detergents, and medications are frequent causes of vulvovaginitis. Some systemic diseases and focal skin disorders may mimic vulvovaginitis or allow it to develop as a secondary process when these conditions involve the vulvar or perineal tissues.[63] Chronic vulvitis in young girls is often associated with atopic dermatitis or psoriasis.[64] Anatomic abnormalities also may be associated with vulvovaginitis. An increased incidence of vulvovaginitis and urinary tract infections has been reported in girls with high posterior commissures.[222] Drainage from an ectopic ureter into the vagina can cause chronic vulvovaginitis and lead to the formation of a vaginal calculus. Labial adhesions were present in 7 percent of girls with vulvovaginitis in one series.[159] Table 42-2 outlines the causes of vulvovaginitis in premenarcheal girls.

Several factors other than those listed in Table 42-2 contribute to the occurrence of vulvovaginal infections in young children. The developing immature labia minora and majora flare outward as a young girl squats or sits. As a result, they do not protect the vestibular and vulvar mucosae from contamination, as occurs later in life. The nonestrogenized, prepubertal vulvar and vaginal epithelium, which consists of only a few layers of cells, is traumatized easily and infected readily; however, no evidence suggests that estrogen deficiency is a causative factor in premenarcheal vulvovaginitis. The alkaline vaginal reaction during childhood also is not as resistant to infection as is the acidic vaginal secretion of postmenarcheal girls and women. Because children frequently do not cleanse themselves properly after defecation, the perineum and vulva often are contaminated by fecal material.

Vulvovaginitis Secondary to Poor Perineal Hygiene. A vulvovaginal infection is considered secondary to poor perineal hygiene when bacteria native to the lower gastrointestinal tract are found in properly obtained cultures from the vagina. In a large series of cases of vulvovaginitis subjected to culture, *Escherichia coli* or other coliform organisms were found in 70 percent of patients in the series.[94] Other studies also have found a higher prevalence of *E. coli* and other enteric organisms in vaginal cultures from girls with vulvovaginitis than in asymptomatic controls.[58] Reappearance and disappearance of premenarcheal vulvovaginitis secondary to poor perineal hygiene are related directly to the appearance and disappearance of coliform organisms in vulvovaginal cultures. The primary role of vulvar and vaginal contamination with fecal material as a result of inadequate cleansing after defecation is supported by the observation that symptoms resolve in most cases when proper perineal hygiene is the only treatment recommended. In children, 15 to 20 percent have recurrences, usually 1 month or more after resolution of the initial episode. In most instances, recurrences can be attributed to poor perineal hygiene.[94]

Children with nonspecific vulvovaginitis secondary to poor perineal hygiene do not have any uniform historical findings. On examination, the vulvar mucosa and outer third of the vagina usually are hyperemic with associated scant, light gray mucoid discharge. Many children wipe themselves from back to front after defecation. In girls, this practice easily results in fecal contamination of the vulvar area. Fecal soiling around the anus or on the perineum or in undergarments can be a clue to the etiology.

Proper cleansing of the perineum and anus after defecation and sitz baths lead to the resolution of symptoms and infection in most cases. Sitz baths (warm water with or without colloidal oatmeal or baking soda) 10 to 15 minutes in duration should be taken 2 to 6 times per day, depending on the severity of the vulvovaginal inflammation.[58] For intense inflammation, wet compresses with Burow solution (1:40) or plain water applied every 3 to 4 hours may be used instead of sitz baths.[7] In mild cases, the vulva may be washed twice per day with water or a mild, unscented, nonmedicated soap. Witch hazel pads may be used for cleansing after defecating and to provide mild analgesia.[190]

Loose-fitting clothing should be worn for several days to a few weeks after the symptoms resolve. Continued wearing of such clothing also may be helpful in preventing recurrences of vulvovaginitis, especially in warmer climates. Instructing parents regarding perineal and

TABLE 42-2 **Etiologic Factors in Premenarcheal Vulvovaginitis**

Bacterial Infections

Nonspecific mixed infections secondary to
- Poor perineal hygiene
- Foreign body in vagina
- Respiratory tract infections
- Skin infections (impetigo)
- Urinary tract infection

Specific nonvenereal infection
- Hemolytic streptococci (groups A, B, F)
- *Escherichia coli*
- *Shigella flexneri, Shigella sonnei*
- *Neisseria meningitidis, Neisseria sicca*
- *Haemophilus influenzae* type b, nontypeable strains
- *Streptococcus pneumoniae*
- *Corynebacterium diphtheriae*
- *Yersinia enterocolitica*
- *Mycobacterium tuberculosis*
- *Moraxella (Branhamella) catarrhalis*
- *Staphylococcus aureus*

Specific venereal infections
- *Neisseria gonorrhoeae*
- *Treponema pallidum*
- *Chlamydia trachomatis*
- Chancroid *(Haemophilus ducreyi)*
- Granuloma inguinale

Bacterial vaginosis
- *Gardnerella vaginalis*
- *Mobiluncus* species

Fungal Infections

Candida albicans

Other yeasts

Dermatophytes

Protozoan and Parasitic Infections

Trichomoniasis

Amebiasis

Enterobius vermicularis

Hirudiniasis

Schistosomiasis

Other parasitic infections (ascariasis, trichuriasis)

Viral Infections

Venereal
- Herpes simplex
- Condyloma acuminatum (papillomavirus)
- Molluscum contagiosum

Involvement as part of systemic infection
- Measles
- Varicella
- Mononucleosis (Epstein-Barr virus)
- Coxsackievirus
- Smallpox

Infestations

Pediculosis

Scabies

Contact Irritation or Allergic Reactions

Bubble bath preparations

Hair shampoos

Vulvar deodorant sprays

Soaps, laundry detergents

Other medications

Vulvar or Perineal Skin Diseases

Local
- Seborrhea
- Lichen sclerosus et atrophicus
- Lichen planus
- Lichen simplex chronicus
- Premalignant leukoplakia
- Erythrasma *(Corynebacterium minutissimum)*
- Bartholinitis
- Skenitis

Involvement as part of a systemic disorder
- Psoriasis
- Bullous pemphigoid
- Atopic dermatitis
- Drug eruption
- Generalized pruritus with excoriation
- Chronic liver disease
- Chronic renal disease
- Metabolic errors
- Psychosomatic
- Crohn disease
- Sjögren syndrome
- Henoch-Schönlein purpura
- Histiocytosis
- Kawasaki disease
- Stevens-Johnson syndrome
- Typhoid
- Zinc deficiency

Physical Factors

Sand (sandbox)

Chemical or thermal trauma

Physical trauma (accidents, abuse, masturbation)

Nylon, rayon underclothing

Tight garments (maceration in warm climates)

Anatomic abnormalities
- Neoplasms (sarcoma botryoides)
- Polyps
- Labial agglutination, adhesion
- Prolapsed urethra
- Ectopic ureter
- Rectal fistula
- Draining pelvic abscess via fistula

Data from references 9, 10, 20, 40, 41, 58, 63, 65, 104, 125, 141, 166, 192.

vulvar cleansing when girls are bathed decreases the likelihood that nonspecific vulvovaginitis will develop. Young girls should be taught proper hygiene and that they should wash their hands before and after urinating and defecating. Shampooing the hair while sitting in a bathtub and using harsh soaps, bubble baths, or other preparations that might lead to chemical irritation of the vulvar skin and vaginal mucosa should be avoided throughout the course of vulvovaginitis.[16,26] The application of powders should be avoided, at least until the acute symptoms have resolved.

As the inflammation and exudate subside over 1 to 2 days, sitz baths may be reduced in frequency and alternated two to four times per day with the application of either calamine lotion or protective ointments, such as zinc oxide. If pruritus is a significant symptom, an oral agent such as hydroxyzine or diphenhydramine may be administered. Topical application of 1 percent

hydrocortisone cream or triamcinolone acetonide cream may be used as the inflammation resolves but should be avoided in the acute phase.[190]

Patients who do not improve after 2 to 3 days of hygienic measures should be reevaluated. Specimens taken from the vagina should be sent for aerobic and anaerobic bacterial cultures, if these were not done initially. Intractable nonspecific vulvovaginal infections that are not caused by foreign bodies, intestinal parasites, or poor perineal hygiene are encountered occasionally. Reducing vaginal pH from an alkaline or neutral to an acid reaction often helps in these difficult cases and may be achieved by the local use of estrogen. Topical estrogens are not recommended for the treatment of routine cases of premenarcheal vulvovaginitis because the results do not seem to be superior to nonhormonal therapies in these cases[94] and prolonged administration may cause isosexual pseudoprecocity. After 7 to 10 days, the vulvar and vaginal tissues usually thicken and a mucoid vaginal secretion may appear.

Oral or parenteral antibiotics may be indicated if symptoms persist for 2 to 3 weeks, or if a specific pathogen that requires antibiotic treatment is isolated. When possible, selection of antibiotic agents and the route of administration should be based on susceptibility testing of organisms isolated from vaginal cultures. Nonspecific vulvovaginal infections generally are benign, superficial, localized mucosal inflammations that usually respond to less potent chemotherapeutic agents when these are needed.

Vulvovaginitis Secondary to Intestinal Parasites. Pinworms *(Enterobius vermicularis)* are the causative factor in many cases of recurrent or intractable nonspecific vulvovaginitis in children.[58] Infection occurs when the worms in the lower bowel crawl out of the anus onto the perineum and migrate into the vagina, where they deposit ova. The pinworms may carry *E. coli* and other coliform bacteria into the vagina, which may lead to vulvovaginitis.

Infestation with pinworms occurs commonly and does not indicate poor hygiene. Pinworm ova may be deposited in playground soil, on toys or books, and on the hands of infected individuals. Infection frequently is asymptomatic. A child with a pinworm infection and vulvovaginitis usually has a history of a chronic vaginal discharge that has recurred despite repeated attempts to eradicate it. Parents may note worms on the perineum of the child and that she awakens at night because of perineal itching. Other family members or the girl herself may have had pinworms previously.

Examination reveals a low-grade inflammation of the vulva and vagina. Excoriations from scratching may be seen on the perineum. Vaginoscopy (if indicated) shows an inflammatory reaction extending to, but not including, the cervix. Vaginal cultures produce a mixed growth of nonpathogenic bacteria, with *E. coli* and other coliform bacteria generally predominating.

The diagnosis depends on finding pinworm ova on smears from the perineum or in the vaginal discharge or a report from parents that worms are visible on the child's perianal skin. A perineal smear is most likely to show the presence of pinworms, but pinworm ova may be detected in a wet smear of vaginal secretions (pinworms Fig. 42-4).

FIGURE 42-4 ■ Pinworm ova discovered in a vaginal smear from a child with intractable vulvovaginitis.

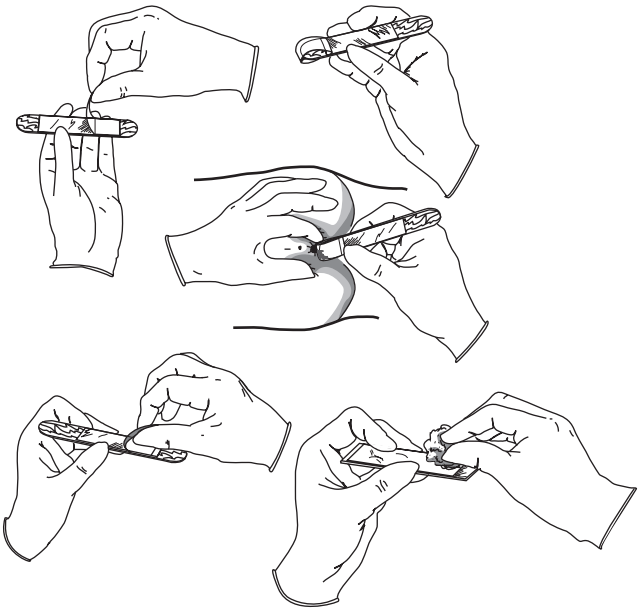

FIGURE 42-5 ■ Technique for obtaining a perianal smear for detection of pinworm ova, using Scotch tape and a tongue depressor.

When a perineal smear for the ova of *E. vermicularis* is to be obtained, the parent is given a wooden tongue blade, a piece of Scotch tape, and a glass microscopic slide. The tape is attached to the tongue blade, adhesive side out (Fig. 42-5), and applied firmly to several areas around the anus. It is removed and applied, adhesive side down, to the glass slide, which is sent to the laboratory for examination.

The type of discharge, the appearance of the vaginal mucosa, or the presence or absence of pruritus does not aid in establishing a diagnosis. A history of a previous pinworm infection in the patient, a member of the family, or a playmate is significant. Pinworms should be suspected when a child has recurrent episodes of intractable nonspecific vulvovaginitis.

Treatment consists of eradicating the pinworms. All members of the family are presumed to be infected and should be treated. Recommended treatment regimens are mebendazole 100 mg orally; albendazole 400 mg orally; or pyrantel pamoate 11 mg/kg base, not to exceed 1 g. Each is given in a single dose and repeated in 2 weeks. The vulvovaginitis caused by coliform organisms carried on pinworms is treated the same as in other cases of nonspecific vulvovaginitis caused by poor perineal hygiene (see earlier discussion).

Vulvovaginitis Secondary to Vaginal Foreign Bodies. Foreign bodies account for approximately 4 percent of cases of vaginal discharge in premenarcheal girls.[7] When a foreign body remains in the vagina for some time, it inevitably causes nonspecific vulvovaginitis. Many types of vaginal foreign bodies, including safety pins, glass beads, coins, beans, bits of crayon, and parts of toys, have been reported. The most common objects are bits of toilet paper or shreds of cloth from nightclothes or bedding (Fig. 42-6).[96,104]

The history does not contribute to the diagnosis unless the child is known to have previously put objects in her vagina. The child usually is brought to a physician because of a profuse, foul-smelling, sometimes blood-tinged discharge. The presence of such a discharge is almost pathognomonic for the presence of a foreign body. Even without a profuse discharge or bleeding, a foul odor from the vagina suggests a foreign body.

Examination reveals inflammation of the vulvar and vaginal mucosa. Although foreign material may be seen when the labia are separated, vaginoscopy often must be performed to explore the full length of the vagina. Rarely, a metallic object that has been in the vagina for some time erodes the mucosa and becomes hidden in granulation tissue. When such a condition is suspected, a radiograph should be obtained. Most foreign bodies, such as glass, plastics, paper, or cloth, are not radiopaque, however, and radiographic examination fails to detect the foreign material. Soft foreign bodies, such as toilet paper, can be flushed out of the vaginal canal.

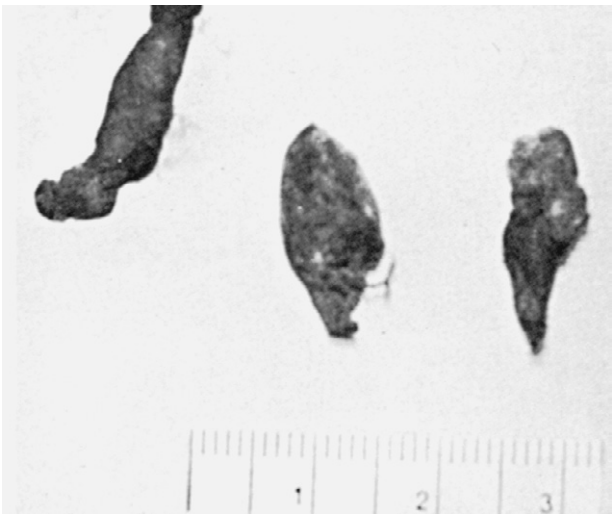

FIGURE 42-6 ■ Bits of paper or cloth are the vaginal foreign bodies most frequently found in children.

The nonspecific vulvovaginitis caused by a foreign body disappears gradually after removal. Recovery can be hastened by using the hygienic treatments previously described. Repeat episodes are common.

Specific Non–Sexually Transmitted Vulvovaginitis

Specific acquired non–sexually transmitted infections are addressed in this section. These include nongonorrheal neisserial vulvovaginitis, group A streptococcal vulvovaginitis, vulvovaginitis secondary to bacteria that colonize the nasopharynx, vulvovaginitis secondary to skin infections, *Shigella* vulvovaginitis, other specific bacterial causes of vulvovaginitis and mycotic (fungal) vulvovaginitis. The majority of infections addressed in this section occur during the prepubertal period. The prepubertal and postpubertal period are addressed for mycotic (fungal) vulvovaginitis.

Nongonorrheal Neisserial Vulvovaginitis. Occasionally, other species of *Neisseria* are the causative agents in cases of premenarcheal vulvovaginitis. These gram-negative, intracellular and extracellular diplococci resemble *Neisseria gonorrhoeae* on stained smears. *Moraxella catarrhalis* also is identical on Gram stain. Gram-negative diplococci should be speciated completely by the microbiology laboratory to avoid misidentifying of nongonococcal diplococci as gonococci and vice versa. Especially for pediatric patients, misidentification can result in serious medicolegal consequences for the family when unwarranted intervention is initiated, or it can result in failure to protect the child's welfare when appropriate measures are deemed unnecessary.[6]

Neisseria sicca, generally considered nonpathogenic, has been isolated from children with vulvovaginal infections that clinically resembled gonorrhea.[218] *Neisseria meningitidis* also has been reported as a cause of vulvovaginitis.[61,80] Nongonococcal *Neisseria* spp. may be considered the cause of vulvovaginal infections when isolated as the predominant flora in the setting of vaginal inflammation and discharge.

Treatment of vulvovaginitis caused by nongonococcal *Neisseria* spp. or *M. catarrhalis* is the same as for *N. gonorrhoeae*. Most nongonococcal *Neisseria* spp. are not resistant to penicillin, but the need for therapy generally is based on the Gram stain finding of gram-negative diplococci, which for therapeutic purposes should be considered gonococci pending culture results. Although data are unavailable, a single dose of ceftriaxone probably should be as effective for these noninvasive *Neisseria* infections as it is for gonorrhea. Chemoprophylaxis, generally with rifampin, should be considered for family members and other contacts in cases of meningococcal vulvovaginitis.

Group A Streptococcal Vulvovaginitis. Group A streptococci are a frequent cause of vulvovaginitis in premenarcheal girls and accounted for 9 to 20 percent of cases in several series.* Most cases occur in girls aged 2 to 7 years, but cases in infants and teenagers have been reported.[21,52,75,201] A marked seasonal variation in incidence in some geographic regions, with peak rates occurring in late fall and winter, may explain the low number of cases of vulvovaginitis caused by group A streptococci in some series.[62,140] The nasopharynx seems to be the primary reservoir for group A streptococci in these girls. Infection may occur from self-inoculation by hand to nose to the vulvovaginal area.[182] The skin also may serve as the source of group A streptococcal vulvovaginitis.[75,201] Preceding or concurrent symptoms of upper respiratory tract infection are uncommon findings, but many girls with group A streptococcal vulvovaginitis have throat cultures positive for *Streptococcus pyogenes*.[75,201] Perineal symptoms have preceded pharyngeal symptoms in some patients.[62] Group A streptococcal vulvovaginitis may occur during the course of scarlet fever.[21,93,94]

The signs and symptoms of group A streptococcal vulvovaginitis often overlap those caused by other bacterial infections, but symptoms usually are abrupt in onset. Most patients seek medical care within 1 week of onset. Vaginal discharge and dysuria are the most common complaints. These girls usually are afebrile. Localized tenderness and an intense, fiery red erythema of the vulvar tissues are frequent findings, but some cases have only mild erythema. Pruritus and excoriation may be present. The discharge usually is seropurulent but may be serosanguineous. The color may be white or green. Petechiae may be present on the vaginal mucosa, and regional papular or scarlatiniform rashes can occur.[62,75,182,201] Acute poststreptococcal glomerulonephritis has been reported in association with group A streptococcal vulvovaginitis.[150] Labial abscesses caused by *S. pyogenes* have been noted rarely in prepubertal girls.[214]

Concomitant streptococcal proctitis and perianal skin infections have been reported.[62,120,197] Perianal pruritus, erythema, and tenderness are common findings.

The diagnosis of *S. pyogenes* infection may be missed if vaginal secretions are not plated onto sheep blood agar or other media that readily support the growth of streptococci.[201] The vulvovaginitis caused by group A streptococci usually shows initial response to oral antimicrobial therapy within 24 hours. A 10-day course of oral penicillin, amoxicillin, or erythromycin generally is sufficient. A second course sometimes is necessary when perianal disease is present.[197] Adjunctive use of the hygienic measures discussed for nonspecific vulvovaginitis hastens clinical improvement. Group B and group F streptococci also have been isolated from girls with acute vulvovaginitis.[187]

Vulvovaginitis Secondary to Bacteria That Colonize the Nasopharynx. Often, a history of an upper respiratory tract infection precedes the onset of vulvovaginitis by a few days. Suspicion that the two conditions are related is strengthened when vaginal cultures yield organisms that commonly colonize the nasopharynx. Vulvovaginitis is assumed to result from autoinoculation of microbes from the nasopharynx to the genitalia. The onset of vulvovaginal symptoms in these infections tends to be acute, the inflammation and discomfort marked, and the discharge less profuse and less purulent than in nonspecific vulvovaginitis.[58]

H. influenzae and *S. aureus* are the species isolated most frequently from cultures.* *Streptococcus pneumoniae* is seen occasionally. *H. influenzae* was the organism isolated most frequently in a series of 200 girls with vulvovaginitis.[159] Acute and chronic cases of *H. influenzae* vulvovaginitis do occur, and the discharge usually is mucoid or mucopurulent, yellow, and odorless. Vulvovaginitis can be caused by serotypes a, b, and c and by nontypeable strains.[94,139] Concurrent otitis media or urinary tract infection may be present. All three of these species occasionally are found in vaginal cultures from asymptomatic children. Their isolation in pure culture from symptomatic girls is what leads to the clinical conclusion of cause and effect.

Vulvovaginitis caused by these organisms often responds to the treatment described earlier for nonspecific vulvovaginitis secondary to poor perineal hygiene. Systemic antibiotics may be required for persistent cases or may be helpful early in severely symptomatic cases. The choice of agent depends on the anticipated or known antimicrobial susceptibilities of the specific organism. The vagina is a well-recognized source of *S. aureus* colonization in cases of toxic shock syndrome associated with this organism. Such cases generally have occurred in adolescent girls and women in association with the use of tampons. Vulvovaginitis caused by *S. aureus* in prepubertal girls has not been reported in connection with toxic shock syndrome. Labial abscesses caused by *S. aureus* have been described in prepubertal girls.[58]

Vulvovaginitis Secondary to Skin Infections. Similar to a child with an upper respiratory tract infection, a child with impetigo or an infected superficial wound may transmit bacteria from the wound to the genitalia by hand contamination. Cultures in such cases usually yield hemolytic streptococci or *S. aureus*. Treatment is the same as that described for nonspecific vulvovaginitis secondary to respiratory tract infections.

Shigella Vulvovaginitis. Vulvovaginitis may be caused by infection with pathogens from the intestinal tract, especially when the organisms are endemic in a community. *Shigella* spp., mainly *Shigella flexneri* and *Shigella sonnei*, seem to account for most of these cases.[20,24,25,49,147] Vaginal discharge without pain, pruritus, or dysuria is the most frequent manifestation of *Shigella* vulvovaginitis. The course can be acute, but discharge that persists for 4 weeks to several months before the diagnosis is made is common. Bloody discharge has been observed in approximately half the cases reported from developed countries, but it was not seen in any of 27 girls with *Shigella* vulvovaginitis in Rwanda between 1988 and 1991.[20,24] The discharge may be purulent and heavy;

*References 40, 41, 52, 54, 94, 166, 192, 201, 214.

*References 40, 41, 137, 159, 166, 192.

occasionally, it is absent. The vulvar tissues usually appear inflamed.

In most instances, *Shigella* vulvovaginitis is not associated with current or recent diarrhea.[20,147] The clinical presentation can be very similar to that of a vaginal foreign body. Local application of triple-sulfa cream (Sultrin) may clear the infection in some cases. Refractory cases have been described, however.[49,147] Systemic treatment with an antibiotic to which the *Shigella* isolate is susceptible is recommended. Trimethoprim-sulfamethoxazole and cefixime are reasonable choices for susceptible isolates; however, most *Shigella* isolates are resistant to ampicillin and trimethoprim-sulfamethoxazole. Ciprofloxacin and ceftriaxone are also effective treatment options.[8,15] As with other causes of vulvovaginitis, adjunctive use of hygienic measures may help resolve the process and prevent recurrence.

Other Specific Bacterial Causes of Vulvovaginitis. Diphtheritic, amebic, and other types of specific vulvovaginitis in children have been reported in the literature.[67,125,158] Most such cases have had associated primary disease elsewhere.

Diphtheritic vulvovaginitis can be the primary site of infection, but most reported cases have been secondary to nasopharyngeal infection. Although diphtheria seldom occurs today, sporadic cases occasionally appear in areas where immunization coverage is inadequate. The vulva is the most common genital site involved in diphtheria,[158] but diphtheritic lesions may occur in the vagina without vulvar involvement. The diagnosis is suspected when a child has the severe systemic symptoms produced by upper respiratory tract diphtheria and a local ulceration covered by a gray adherent membrane; it is confirmed by finding *Corynebacterium diphtheriae* in discharge from the lesion.[56] Treatment of diphtheria is the same regardless of the site of the infection and is discussed in Chapter 90.

One case of vulvovaginitis with *Yersinia enterocolitica* isolated as the predominant organism was reported in a 4-year-old girl who also had a positive stool culture and associated fever and abdominal pain but no diarrhea.[216] In other members of the community in which she lived, diarrhea developed with cultures positive for *Y. enterocolitica.* The outbreak was linked to contaminated food. Infections with this organism may be missed because special culture techniques are required for isolation.

Rarely, ulcerative vulvovaginitis caused by *Entamoeba histolytica* or related to typhoid fever has been reported. Generally, specific genital infections with pathogenic organisms usually found in the gastrointestinal tract are the result of fecal contamination of the vulva and vagina. Treatment of infections caused by *E. histolytica* is described in Chapter 209.

Mycotic (Fungal) Vulvovaginitis. *Candida albicans* and *Torulopsis glabrata* are the yeastlike fungi found most often in the vagina. *C. albicans* is responsible for 80 to 95 percent and *T. glabrata* for 3 to 16 percent of fungal infections. Other *Candida* spp. are detected less often in the vagina but can be pathogenic. *Candida tropicalis*, similar to *C. albicans*, produces systemic infection in immunosuppressed hosts.

Prepubertal. *C. albicans* and other fungi can cause vulvovaginitis in infants and children. Although these infections can occur in any child, children with a history of recent antibiotic use, uncontrolled diabetes mellitus, or immunosuppression are at an increased risk for development of fungal vulvovaginitis. In children with recurrent or persistent infection, especially with no history of antibiotic use, immunosuppressive conditions, such as diabetes or human immunodeficiency virus (HIV) infection, should be considered. Mycotic infections are not considered sexually transmitted infections, but they are discussed in this section because they can cause genital infections.

C. albicans and other fungi have been isolated from the vagina in asymptomatic and symptomatic girls. In a study examining the microbiology of the vagina, yeast was cultured from 48 percent of girls aged 2 months to 2 years, from 12.5 percent of girls aged 3 to 10 years, and from 35 percent of girls aged 11 to 15 years.[96] *C. albicans* (37%) and *C. tropicalis* (26%) were the species most frequently isolated, but *Candida parapsilosis*, *T. glabrata*, non-*Candida* yeast species, and other *Candida* spp. were isolated as well.

In studies evaluating prepubertal girls with vulvovaginitis, fungi have been recovered at varying rates. In one study, *C. albicans* was isolated from 25 percent of 31 symptomatic prepubertal girls with an abnormal vaginal discharge or vulvovaginitis, whereas only 3 percent of asymptomatic girls had *C. albicans* isolated.[73] Another study found different results, with none of the 50 asymptomatic girls and only 2 percent of the 50 girls with vulvovaginitis having *C. albicans.*[112] Similarly, in a study evaluating girls younger than 12 years with vaginal complaints, only 3 percent of the 74 girls had *C. albicans* isolated.[187] Neither of these groups of girls had a discharge on examination, and both had been treated recently with antibiotics. In a study that examined recovery of microorganisms from girls with vaginitis, 8 percent of the vaginal cultures of the 35 girls evaluated grew yeast.[79] In these latter two studies, assessing the role of yeast in the disease is difficult because there was no control population for comparison.

Mycotic vulvovaginitis causes severe vulvar and vaginal itching; usually, the patient does not have an excessive discharge. The discharge is white, thick, and curdled and has a yeasty sour odor. The patient may have pain during and after voiding or external dysuria as a result of urine coming in contact with excoriated areas on the urethra and vulva. Young children with fungal vulvovaginitis have similar symptoms. In diapered children, an erythematous rash in the child's diaper area may be noticed. If the condition has been long-standing, the edema, secondary infection, and repeated scratching may produce thickened and fissured lesions closely resembling chronic eczema or lichen sclerosus et atrophicus (Fig. 42-7).

Postpubertal. Several factors play roles in causing the increased incidence of vaginal candidiasis after menarche. These are menstruation, fecal contamination of the vulva, wearing tight-fitting underclothes, widespread use of antibiotics, and the use of oral contraceptives. Other predisposing factors include pregnancy, obesity,

FIGURE 42-7 ■ Mycotic vulvovaginitis. The child has diabetes.

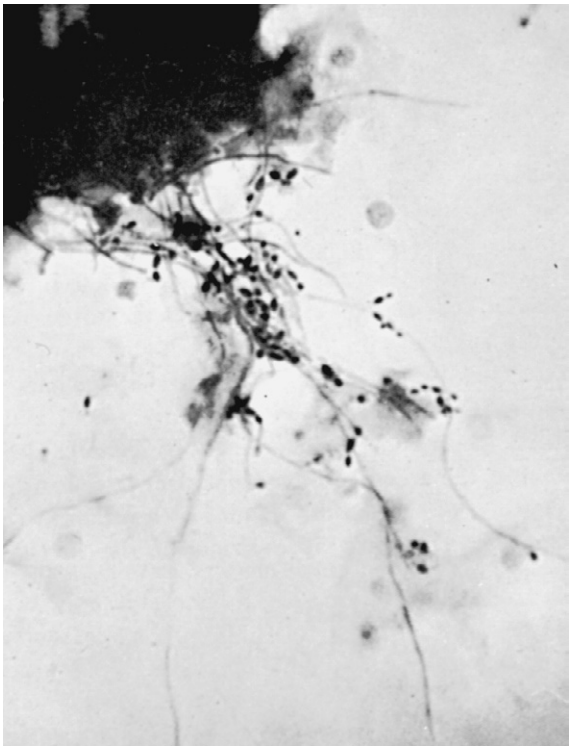

FIGURE 42-8 ■ Hyphae of *Candida albicans* discovered on a wet smear of vaginal discharge.

uncontrolled diabetes mellitus, immunosuppressive therapy, and heroin or other drug addiction.[226]

Mycotic vulvovaginitis causes severe vulvar and vaginal itching. The discharge is white, thick, and curdled and has a sour odor. The patient may have external dysuria. Examination in the acute stage reveals intense inflammation of the vulva and vagina with shiny and beefy red mucosa with linear excoriations and edema. Long-standing infection can cause lichenification and hyperpigmentation of the perineal skin. *C. albicans* typically forms white plaques scattered over the inflamed surfaces. *C. tropicalis* produces a cottage cheese–like discharge similar to that found with *C. albicans*. Vaginal pH usually is normal (<4.5).[226]

Diagnosis. The diagnosis in all age groups is frequently based on clinical findings and can be established by a vaginal saline wet preparation under microscopy and by finding hyphae and buds of the fungus in vaginal fluid (Fig. 42-8) in the curdled discharge. If debris and cellular material render identifying the fungus difficult, a smear using 10 percent potassium hydroxide solution is helpful. The potassium hydroxide solution dissolves other extraneous material without affecting the fungus. Even with an experienced microscopist, this method yields a sensitivity range of 40 to 86 percent in symptomatic girls; however, the yield may be only 40 percent. Further confirmation can be obtained by identifying fungus by culture of material from the vagina or vulva on Sabouraud or Nickerson media, but this is generally unnecessary.

Treatment. Several modes of therapy can be used for the management of fungal vulvovaginitis in premenarcheal females.[58] Numerous antifungal creams, including nystatin, miconazole, clotrimazole, or terconazole, are available. The creams should be applied as prescribed to the affected area after cleansing. In diapered children, the cream should be applied with each diaper change.

Curing fungal infections often is difficult in children who are taking antibiotics or who receive repeated courses of antibiotic therapy. In such cases, a 1-mL dose of nystatin suspension (Mycostatin), 100,000 U/mL, can be injected into the vagina three times per day for 10 days in infants and small children. In addition, the suspension should be administered at the same dose orally four times daily. Fluconazole (Diflucan) also can be administered as a one-time oral dose. A second dose may need to be administered for severe infections.[58]

In adolescents a variety of imidazoles are available as over-the-counter vaginal creams, tablets, and coated tampons. Intravaginal treatment with one 100-mg vaginal tablet of clotrimazole every night for 7 days produces a cure rate of 90 percent. Comparable cure rates are observed with 100 to 200 mg of clotrimazole or miconazole (2 tablets) for 3 days. The shorter regimen may result in better compliance. Creams and tablets are equally effective.[35] Oral fluconazole 150 mg as a single dose is an effective preparation for the treatment of uncomplicated vulvovaginal candidiasis.[35] Low-dose prophylactic treatment also may be appropriate in these cases. If recurrent unexplainable or resistant infection occurs, diabetes mellitus should be suspected.

SPECIFIC SEXUALLY TRANSMITTED VULVOVAGINITIS

Specific sexually transmitted vulvovaginitis in this section includes discussion of gonorrhea and chlamydia in prepubertal girls and trichomoniasis and bacterial vaginosis in prepubertal and postpubertal females. Gonorrhea and *Chlamydia* infections in postpubertal period females cause

cervicitis instead of vulvovaginitis and are addressed under the discussion of cervicitis.

Gonorrhea

Prepubertal

Gonococcal infections of the prepubertal genital tract are manifested as vulvovaginitis.* The alkaline environment of the unestrogenized vaginal tissues of young girls apparently limits spread of infection to the upper genital tract. Gonorrhea is found less commonly in children now than in the past but must be considered whenever a girl has vulvovaginitis.

In infants, perinatal nonsexual transmission is considered the most likely cause of gonococcal infection. Branch and Paxton[23] found that in 1- to 11-month-old infants, all the mothers were found to have gonococcal infection and no history of sexual contact could be elicited. The authors concluded that transmission of the infection was perinatal, from freshly contaminated hands, or through fomites.

Prepubertal children with gonococcal infection frequently are found to have a history of sexual contact.[107] The rate of eliciting a history of sexual contact in prepubertal children with gonorrhea ranges from 36 to 93 percent.[23,66,109,110] Branch and Paxton[23] reported that 93 percent of children aged 1 to 9 years with gonorrhea had sexual contact with relatives in the household. Ingram and colleagues[109,110] found that 35 percent of 1- to 4-year-old children and 100 percent of children older than 4 years with gonorrhea reported having sexual contact with an older male family member. Folland and coworkers[66] elicited a history of sexual contact from 34 percent of children with gonococcal urethritis and vaginitis.

Other infected adults and children often are found in an infected child's environment.[163] Testing of household members can detect infected adults at a rate of 18 to 29 percent.[5,149] In a retrospective study of 14 Native Alaskan children with gonococcal infection, 3 reported having sexual contact. Seven children slept with their parents, one or both of whom had gonorrhea; the authors assumed that these children acquired the infection by nonsexual means.[189] Nonsexual transmission conceivably occurs in children who sleep and bathe with their parents.

N. gonorrhoeae has been shown to survive for 20 to 24 hours in infected secretions on towels and handkerchiefs.[199] Although *N. gonorrhoeae* has survived on toilet seats for 2 hours, no gonococci were recovered from toilet seats in public restrooms or in a clinic for STI.[74,169] Nonsexual transmission to adults is rare.

Sexual transmission is the more common and most likely mode of transmission, however.[86] Thus, the presence of gonorrhea should be considered diagnostic of sexual abuse. An investigation for sexual abuse must be pursued in a child with gonorrhea by reporting the case to the appropriate legal authority (Table 42-3).[35]

N. gonorrhoeae was the most common cause of vulvovaginal discharge among prepubertal girls in Rwanda in the late 1980s. Sexual contact was considered likely in all cases because of a cultural belief that a man with a purulent urethral discharge could be cured by rubbing his penis on the external genitalia of a prepubertal girl.[20] In a prospective study of girls 12 months to 12 years of age in the mid-1990s in Cincinnati, Ohio, who had vaginal discharge and no suspicion of sexual abuse, 4 of 43 had positive cultures for *N. gonorrhoeae*.[187] Such cases should lead to investigation for probable sexual abuse.

The acute stage of gonorrheal vulvovaginitis is characterized by inflammation and a purulent discharge. The child may complain of vulvar discomfort, dysuria, frequent urination, and pain on walking. The child usually is well otherwise. Asymptomatic vaginal infection is rare. On examination, the vulvar tissues are edematous, hyperemic, and covered by a profuse, thick, yellowish discharge that exudes from the vagina. The entire vaginal mucosa is inflamed.

The urethra, paraurethral glands, and major vestibular (Bartholin) glands rarely are involved in a premenarcheal gonorrheal infection. Vulvovaginal infections, including gonorrhea, in prepubertal children rarely, if ever, affect the upper genitalia (uterus, uterine tubes, ovaries, or pelvic peritoneum). Symptoms suggestive of pelvic peritonitis have been reported in premenarcheal children who had gonorrheal vulvovaginitis; all the patients recovered promptly after the administration of penicillin.[33,68]

The acute phase of infection lasts for a few weeks, after which most of the symptoms, except the discharge, disappear. The vulvar and vaginal tissues may remain hyperemic and macerated in some cases. The discharge becomes scanty and seropurulent, which may persist chronically.

Diagnosis

The diagnosis of gonorrheal vulvovaginitis and its differentiation from other types of vulvovaginitis are established by vaginal smears and cultures. Specimens from the pharynx and rectum to test for *N. gonorrhoeae* also should be obtained. Because of the potential medicolegal use of the test results for *N. gonorrhoeae* among children, standard culture systems should be used for the diagnosis of *N. gonorrhoeae* in children. More recently nucleic amplification testing for gonorrhea using urine and vaginal swabs was conducted in 485 premenarcheal girls with alleged sexual abuse from four cities in the United States. The sensitivity of urine nucleic amplification testing for gonorrhea relative to vaginal swabs was 100 percent.[19] As a result, the Centers for Disease Control and Prevention (CDC) has approved use of nucleic amplification testing of vaginal or urine specimens in girls suspected of having experienced sexual abuse, as long as specimens are retained for additional testing if necessary.[35]

Treatment

The presence of gram-negative intracellular diplococci in vaginal smears from a child with a history of exposure or with typical clinical findings is sufficient reason to start treatment, but it does not establish a definitive

TABLE 42-3 **Sexually Transmitted Diseases in Prepubertal Children: Modes of Transmission and Implications for Child Sexual Abuse**

Infectious Agent	Persistence After Perinatal Acquisition	STI Rate in Alleged Sexual Abuse Cases (%)	Alleged Sexual Abuse Rate in STI Cases	Infections in Household Members of Infected Children	Survival on Fomites	AAP CCAN 2005 Guideline Recommendations for Abuse Report	Other Comments
Neisseria gonorrhoeae	Up to 1 yr old[23]	5-7[49]	35%, 1-4 yr old[109] 100%, >4 yr old[109] 93%, 1-9 yr old[23,66]	18%-29% of adults in household[87,149,192] (abuse was thought unlikely in these series)	24 hr on wet fomites; 2 hr on dry fomites. None from public toilet seats[74,169]	Diagnostic for abuse; report to Child Protective Services*	Although fomite transmission can occur, sexual transmission must be considered the likely mode, unless strong evidence of an alternative mode is found. Fomite or maternal nonsexual transmission plausible <1 yr old[23]
Chlamydia trachomatis	Up to 6 yr old[178,211] Rectal and vaginal sites up to 54 wk	6-7[69,108,110] 6-8 cases vs. 0 controls[107,110]	75%		No data	Diagnostic for abuse; report to Child Protective Services*	Perinatal acquisition likely <1 yr old; if >1 yr old, genital infection strongly suggests sexual transmission.[107,108,110]
Trichomonas vaginalis	Up to 1 yr old [43,138]	0 cases vs. 0 controls[71,191]	Case report[114]	Case report with no contacts[33] 43% fathers, 72% mothers, with no history of sexual abuse elicited (Poland)[123]	Up to 6 hr on wood surface and in discharge.[118] Isolated from bathing implements[152], bathing waters, mud baths[123]	Highly suspicious for abuse; report to Child Protective Services*	If >1 yr old, genital infection strongly suggests sexual transmission. Bathing in tanks or rivers may increase infection risk in girls (India).[37] Has been isolated from mud baths, warm mineral waters, water from toilets.[49,123]
Bacterial vaginosis (*Gardnerella vaginalis*)	No systematic studies; colonization at birth potentially persists for years	7-13 by Amsel criteria[87] *G. vaginalis* 15 cases vs. 1-4 controls[15,70]	*G. vaginalis* 6%-15%[15,70]	None	None	Inconclusive; conduct medical follow-up	*G. vaginalis* can be found as part of normal flora in nonabused virginal children

TABLE 42-3 **Sexually Transmitted Diseases in Prepubertal Children: Modes of Transmission and Implications for Child Sexual Abuse** (Continued)

Infectious Agent	Persistence After Perinatal Acquisition	STI Rate in Alleged Sexual Abuse Cases (%)	Alleged Sexual Abuse Rate in STI Cases	Infections in Household Members of Infected Children	Survival on Fomites	AAP CCAN 2005 Guideline Recommendations for Abuse Report	Other Comments
Herpes simplex virus (genital sites)	Symptomatic congenital infection usually develops within first 6 wk of life		Case reports only	Case report only (mother with an infected finger)[116]	2 hr on latex gloves, toilet seats; 24 hr on speculum; 72 hr on gauze[129]	Suspicious for abuse; report to Child Protective Services*†	Autoinoculation from oral lesions is possible,[148] but fomite transmission is unlikely because it requires direct contact of viable virus with broken skin or mucous membranes
Human papillomavirus‡ (anogenital warts)	Up to at least 3 yr old and probably years longer[48]	27-90[38,97]		Digital infection[183]	None	Suspicious for abuse; report to Child Protective Services*§	The possibility of sexual abuse should be considered when oral warts or laryngeal papillomas are found in older children
Syphilis	Months to years if untreated	0-5[49,76,107]	Case reports		Unlikely, based on difficulty in culturing the microbes, but no data	Diagnostic for abuse; report to Child Protective Services*	Infection not known to be congenital should be considered sexually transmitted. Clinical manifestations (e.g., late congenital syphilis) may be helpful in discerning mode in some cases[3]

Modified from Chacko M, Staat MA, Woods CR. Genital infections in childhood and adolescence. In: Feigin RD, Cherry JD, Demmler GJ, Kaplan SL, eds. *Textbook of Pediatric Infectious Diseases*. 5th ed. Philadelphia: W. B. Saunders; 2009:575; and Kellogg N, American Academy of Pediatrics Committee on Child Abuse and Neglect. The Evaluation of sexual abuse in children. *Pediatrics* 2005;116:506-512.

*Or other local agency mandated to receive reports of suspected child sexual abuse.

†Report unless there is a clear history of autoinoculation. Type of herpes simplex virus (1 vs. 2) is generally not helpful in determining whether acquisition was by abuse or autoinoculation, although presence of type 1 may increase the likelihood of nonsexual transmission.

‡Laryngeal papillomas in young children are likely perinatally acquired.

§Some experts do not believe reporting is warranted in all cases. In children younger than 3-4 years old for whom a thorough evaluation by an experienced child sexual abuse investigator reveals no concerns of abuse, reporting to Child Protective Services may be unnecessary. Close medical follow-up may be appropriate. Physicians must be clear when reporting that anogenital human papillomavirus is not always acquired by sexual abuse even in older children.

STI, Sexually transmitted infection.

diagnosis. Further details on treatment are addressed in Chapter 89.

Chlamydia

Prepubertal

Sexual abuse as a potential mode of transmission of *C. trachomatis* infection should be considered in children older than 1 year.[69,89] An investigation for sexual abuse must be pursued in a child with *Chlamydia* infection by reporting the case to the appropriate legal authority (see Table 42-3).[35]

In a retrospective study, Ingram and associates[108] found that 6 percent of girls who allegedly were sexually abused and no girls who denied sexual abuse had *C. trachomatis* infection. Except for one child, all the children in the control group were determined later to have been sexually abused. In a prospective study, Ingram and associates[107,110] found *C. trachomatis* in 8 percent of girls with a history of sexual abuse compared with none in girls with no history of sexual abuse. In the former group, three girls also were found to have rectal infection and one to have pharyngeal infection.

Perinatally acquired genital *Chlamydia* infection is a strong possibility in children younger than 1 year. Perinatal transmission is possible in children aged 3 years. After 1 year of age, however, sexual transmission should be considered diagnostic of sexual abuse in children with genital *Chlamydial* infection.[34] An investigation for sexual abuse must be pursued in a child in whom genital chlamydial infection is diagnosed.[34,89] Studies have evaluated the presence of *C. trachomatis* on fomites and its coexistence in family members of infected children.

Although *C. trachomatis* appears to be an uncommon cause of vaginitis in prepubertal girls, vaginal infection with *C. trachomatis* can occur in children with or without a known history of sexual activity and should be considered in the evaluation of a child with vaginal symptoms. Only a few studies have evaluated young children for *C. trachomatis.* These studies have involved mostly children being evaluated for sexual abuse or vulvovaginal symptoms, or both, and some have included a control group in an attempt to control for either a history of sexual activity or vaginal symptoms.

In studies evaluating premenarcheal children with vulvovaginitis, recovery of *C. trachomatis* has been low in children with symptoms and healthy control groups. In one study, none of the 35 children with symptoms had *C. trachomatis*, whereas 1 of 35 without symptoms had *C. trachomatis* isolated.[156] In another study conducted in a pediatric gynecology clinic, 4 of 29 (14%) premenarcheal girls were found to have *C. trachomatis.*[30] All four had a homogeneous white discharge, and one had a bloody discharge. Sexual abuse occurred in two of the children and was considered possible in another. In a Cincinnati study evaluating vaginitis in girls younger than 12 years in whom sexual abuse was not suspected, none of the 87 children had a positive culture for *C. trachomatis.*[187] Similarly, in a smaller study of 11 girls with vaginitis, none was found to have *C. trachomatis.*[170]

In studies evaluating children suspected of being sexually abused, rates of recovery tend to be higher than those seen in children with vaginitis. In one study, a history of sexual abuse was discovered in two control children only after *C. trachomatis* was identified.[84] Initially, 2 percent of children with a history of sexual abuse versus 4 percent of healthy controls had positive vaginal cultures for *Chlamydia*. On further questioning, however, the two children in the control group with *C. trachomatis* were siblings who were sexually abused 3 years earlier, changing the rate of *C. trachomatis* vaginal infection in the sexual abuse group to 6 percent and decreasing the rate in the control group to zero. This misclassification, if not discovered, would have changed the conclusion of the study, which suggested that similar rates of *C. trachomatis* infection occur in children with and without a history of sexual contact. This incidence illustrates the importance of thoroughly investigating the possibility of sexual abuse whenever a sexually transmitted pathogen is isolated in a young child. In a Cincinnati study evaluating children for sexual abuse, rates were low in prepubertal girls compared with pubertal girls (0.8% vs. 7%),[191] whereas in a study in Raleigh, North Carolina, 6 percent of sexually abused girls younger than 12 years versus none of control children had *C. trachomatis* isolated from their vagina.[110] Four of the 10 children in the latter study had a vaginal discharge.

The highest rates of *C. trachomatis* infection were seen in a Los Angeles study, in which 47 prepubertal girls were examined for alleged sexual abuse and 17 percent had *C. trachomatis* isolated from vaginal specimens.[69] The variation in rates among studies may reflect differences in the prevalence of *C. trachomatis* in different communities. Although coinfection with *C. trachomatis* has not been studied well in prepubertal children, experience from adult populations has shown that it should be suspected in children with *N. gonorrhoeae* infection. In one study in prepubertal girls, 30 percent with *N. gonorrhoeae* also tested positive for *C. trachomatis.*[170]

One possibility is that a positive chlamydial culture in a young child, especially a child younger than 3 years, may be due to persistence of perinatal infection. *C. trachomatis* has been isolated from the conjunctiva, nasopharynx, vagina, and rectum of infants born to infected mothers.[179] Subclinical infections have been reported in 14 percent of infants of mothers with active *C. trachomatis* infection.[178] Many infants infected with *C. trachomatis* at birth remain infected for 372 days in the vagina; 383 days in the rectum; and 866 days in the conjunctiva, nasopharynx, and oropharynx.[17] Persistent chlamydial infection of the pharynx in infants can persist for 2 years.[17] Persistence of perinatal infection for 18 months and for 6 years has been reported in other studies as well.[134,177,211] Although persistence of perinatal infection can occur, when *C. trachomatis* is identified in vaginal specimens, sexual abuse still must be suspected strongly.

In contrast to prepubertal gonorrhea infections, chlamydial vaginitis in children often seems to be asymptomatic. Because of study design issues in evaluating children with *C. trachomatis* infection, in which only children with a history of sexual abuse or vaginal symptoms, or both, are included, fully understanding the spectrum of

symptoms seen in young children is difficult. In one study evaluating symptomatic children with *C. trachomatis* vaginal infection, 25 percent had a vaginal discharge and 12 percent had vaginal bleeding.[69]

Diagnosis

Numerous diagnostic methods for *Chlamydia* are available.[18] Direct tissue culture isolation of *C. trachomatis* remains the gold standard and is the only test that should be used in prepubertal children or in cases in which sexual abuse is under consideration.[35] Culturing for *Chlamydia* requires isolation of the organism in tissue culture and confirmation of the characteristic intracytoplasmic inclusions by fluorescent monoclonal antibody staining.[35] Although the specificity of tissue culture approaches 100 percent, tissue culture is only 70 to 85 percent sensitive in contrast to DNA amplification techniques.[18] The low recovery rate in studies of prepubertal children may be due to the low sensitivity of tissue culture or the use of vaginal cultures in young children. Isolation rates from the vagina usually are lower than rates of recovery from the endocervix.[136]

Nonculture tests for *Chlamydia*, including enzyme immunoassays, direct fluorescent antibody tests, DNA hybridization, and DNA amplification tests, have not been field-tested for large numbers of vaginal specimens or rectal or pharyngeal specimens from premenarcheal girls. False-positive results have been reported in vaginal specimens for some of these tests in children, and these tests should not be used in premenarcheal children.[86,161] False-positive results probably are caused by cross-reactivity with common anogenital organisms, such as group A and B streptococci, *N. gonorrhoeae*, *G. vaginalis*, *E. coli*, and *Proteus*, *Acinetobacter*, and *Staphylococcus* spp.[121,172,174,175,210]

However, more recently, nucleic amplification *Chlamydia* testing using urine and vaginal swabs was conducted in 485 premenarcheal girls with alleged sexual abuse from four cities in the United States. The sensitivity of urine nucleic acid amplification (NAAT) for chlamydia relative to vaginal swabs was 100 percent.[19] As a result the Center for Disease Control and Prevention has approved use of NAAT testing of vaginal or urine specimens in girls suspected with sexual abuse, as long as specimens are retained for additional testing if necessary.[34]

Treatment

Treatment for *Chlamydia* infection is addressed in Chapter 193.

Trichomoniasis

Trichomonas vaginalis is a triflagellated protozoan (Fig. 42-9). The organism, which is larger than a polymorphonuclear leukocyte, has a distinctive vibrating or whiplike movement when seen microscopically in fresh wet smears taken from the vagina. It quickly succumbs to reduction of the pH, drying, cooling, and changing the osmotic pressure of the fluid surrounding it. Most infections are encountered in sexually active adolescents and young adult women. Chapter 214 addresses trichomoniasis, including epidemiology, in more detail.

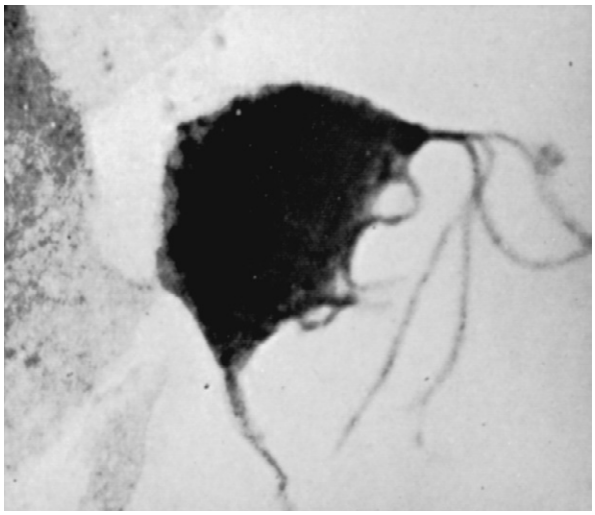

FIGURE 42-9 ■ *Trichomonas vaginalis* is a triflagellated protozoan that, when motile, is identified easily in wet smears of vaginal discharge.

Prepubertal

Vaginal trichomoniasis is reported infrequently in prepubertal children. This low prevalence may be accurate or could be due to lack of appropriate testing or limitations of the diagnostic techniques used in studies in prepubertal children.

Trichomoniasis in newborns through the acquisition of *T. vaginalis* from the mother's vagina during delivery, with recovery of *T. vaginalis* from urine, vaginal, and respiratory tract specimens, has been described in several case reports.* The prevalence of *T. vaginalis* in healthy, vaginally delivered infants of mothers with *T. vaginalis* is unknown. In one study of 868 infants, *T. vaginalis* could not be identified in any of the 14 female infants of mothers in whom *T. vaginalis* was diagnosed. The overall prevalence of *T. vaginalis* was 4 percent, but the denominator of mothers of female infants was not described.[22] In another study of 984 female infants, direct smear or culture (or both) of infant vaginal specimens identified 3 infants with *T. vaginalis*, a prevalence of 0.3 percent.[6] Of the 3 infants, 2 had a vaginal discharge. The overall prevalence of infection in the mothers of the 984 infants was not reported. Of the three infants with *T. vaginalis*, one mother had a history of vaginal discharge and a negative direct smear for *T. vaginalis*, and the other two mothers had no history of *T. vaginalis*. In conclusion, transmission of *T. vaginalis* in infants aged 1 year probably is perinatal.

The mode of transmission in children older than 1 year is controversial. Two cases of *T. vaginalis* infection in premenarcheal girls who were sexually abused have been reported.[113] Numerous reports confirm the occurrence of *T. vaginalis* outside the newborn period in prepubertal girls evaluated for vaginitis. The prevalence of

*References 4, 22, 43, 46, 131, 138, 162, 196.

T. vaginalis in prepubertal girls with vaginitis but no history of sexual abuse ranged from 0 to 4 percent.[94,112,156,187] In studies with a healthy control population,[79,94,112] *T. vaginalis* was not identified in any of the children in the asymptomatic control group.

T. vaginalis has been described in varying frequency in sexually abused prepubertal girls. A case report described *T. vaginitis* in two sexually abused children with vaginal discharge.[113] In studies systematically evaluating children for sexual abuse regardless of symptoms, *T. vaginalis* has not been recovered. In an Australian study evaluating 160 children younger than 10 years and 95 healthy age-matched controls, none of the children had *T. vaginalis* isolated from vaginal cultures.[71] Similarly, none of the 119 prepubertal girls evaluated for sexual abuse in a Cincinnati, Ohio, study had *T. vaginalis* identified by urinalysis or wet mount of vaginal secretions.[191] Without additional studies using culture techniques and conducted in diverse populations of prepubertal girls, determining the true prevalence of *T. vaginalis* in prepubertal girls who have vaginitis, with or without a history of sexual abuse, is difficult.

One case report suggests that *T. vaginalis* could be transmitted within a family without sexual abuse or contact.[2] In this report, *T. vaginalis* was diagnosed in the mother, and her three prepubertal daughters were symptomatic with a vaginal discharge. Two of the three girls had *T. vaginalis* identified on wet-mount evaluation of their vaginal specimens. They had no history or evidence of sexual abuse, the father was asymptomatic, and microscopy of an early morning urine specimen was negative for *T. vaginalis*.

A study from Poland found one case of *T. vaginalis* infection in children aged 2 to 7 years and a significantly higher number of cases in 8- to 10-year-old girls. The numbers increased even further for children older than 10 years, suggesting a strong association between *T. vaginalis* and the presence of an estrogenic environment, which promotes glycogen production and decreases vaginal pH.[123]

The Polish investigation tested families of women infected with *T. vaginalis* and found that almost a third of their sexual partners and 8 percent of the children (mostly girls) had *T. vaginalis*. When families of men infected with *T. vaginalis* were tested, 91 percent of their sexual partners and 13 percent of the children had *T. vaginalis*. When families of children (mostly girls) infected with *T. vaginalis* were tested, 72 percent of the mothers and 43 percent of the fathers had the infection. The investigators considered that the infection in the latter group originated from mothers and that the primary mode of transmission was nonsexual (beds, sponges, towels, overcrowding). Information regarding sharing of potentially infected fomites, sexual abuse, or physically intimate behavior between parents and children was not gathered in these cases.[123]

Although *T. vaginalis* has been known to survive on fomites in controlled experiments, its ability to spread by these means is unknown. No cases of adults being infected by fomites have been documented. *T. vaginalis* has been found to survive for 6 hours on droplets of discharge and enameled surfaces of wood blocks.[118] It has been isolated from droplets of water splashed from toilets containing the urine of an infected individual.[32] *T. vaginalis* also has been found to survive in mud baths, bathing waters, and warm mineral waters and on moist bathing implements.[123,152] In rural India, a survey found that young girls who bathed in tanks or rivers had a significantly higher risk for acquiring *T. vaginalis* than did girls who used pipe or well water.[37]

In summary, *T. vaginalis* conceivably is transmitted to children nonsexually. The likelihood of perinatal transmission is high in infants younger than 1 year. A child or an infant younger than 1 year with *T. vaginalis* also may have been sexually abused. In a child older than 1 year, the probability of sexual abuse must be considered highly suspicious, and the case must be investigated and reported. Perinatal transmission and transmission of infection through fomites should not be assumed without an investigation for sexual abuse (see Table 42-3).[35]

Although these cases may have resulted from transmission within a family without sexual abuse, identification of *T. vaginalis* in a prepubertal child outside the newborn period should prompt further medical and social evaluation for sexual abuse. Additionally, if *T. vaginalis* is recovered from a child, the child should be evaluated for other STIs, including syphilis, *N. gonorrhoeae*, *C. trachomatis*, hepatitis B, and HIV infection.[58]

Postpubertal

Trichomoniasis is common and frequently is asymptomatic in sexually active adolescents (see Chapter 214). When it is symptomatic, patients complain of a profuse, irritating discharge. The discharge and the pruritus tend to be more severe just before and immediately after a menstrual period. Patients occasionally report dysuria and abdominal pain. Recurrent exacerbations of the infection occur commonly.

Examination reveals diffuse vulvitis with erythema and excoriations and copious leukorrhea that covers the vulvar tissues. The discharge typically is frothy or bubbly, grayish yellow, and watery or mucopurulent. It has a pH of 5.0 to 7.0 and an acrid or musty odor. A "strawberry" or punctate vaginal eruption with hemorrhagic spots has been described as being typical of trichomoniasis. Such eruptions frequently are not present, however, even in severe cases. More often, diffuse inflammation causes the vaginal mucosa to be brilliant red.

Diagnosis

The diagnosis of trichomoniasis usually is confirmed clinically by finding trichomonads in a wet saline smear of vaginal fluid. It is important that the slide be viewed under the microscope (dry high power) promptly because the organisms do not remain viable for long outside the vagina and are difficult to detect when they cease to be motile. The observer sees numerous ovoid-shaped, motile organisms (see Fig. 42-9). The sensitivity of this test with immediate evaluation is 60 to 70 percent. A Papanicolaou (Pap) smear to detect trichomoniasis is not recommended because of the high rate of error in identifying trichomonads in stained smears. Other methods used to diagnose

trichomoniasis include isolation by special culture medium, direct fluorescent immunoassay, and nucleic acid amplification test. Culture is the most sensitive, but it is not routinely available. The nucleic acid amplification test is available in some clinical settings (point-of-care test); however, a false-positive result may occur in low-prevalence populations.[35]

Treatment

Treatment for trichomoniasis is addressed in Chapter 214.

Bacterial Vaginosis

Bacterial vaginosis (previously termed *nonspecific vaginitis* in adult women) is a cause of vaginal discharge in adolescents and occasionally may be seen in premenarcheal girls. Bacterial vaginosis is caused by a change in the relative proportions of bacteria in the vaginal flora: an overgrowth of anaerobes, especially *Bacteroides* and *Mobiluncus* spp., *G. vaginalis*, and *M. hominis;* and a decrease in hydrogen peroxide–producing lactobacilli.[10] Identification of *G. vaginalis* by culture of the vaginal discharge is not diagnostic because *G. vaginalis* may be present in girls with or without bacterial vaginosis.[35]

The clinical criteria used for establishing the diagnosis of bacterial vaginosis are the presence of three of four findings: a grayish homogeneous discharge, the presence of clue cells on a wet-mount evaluation (Fig. 42-10), a pH greater than 4.5, and a positive amine test result (amine or fishy odor when vaginal secretions are mixed with 10% potassium hydroxide).[35]

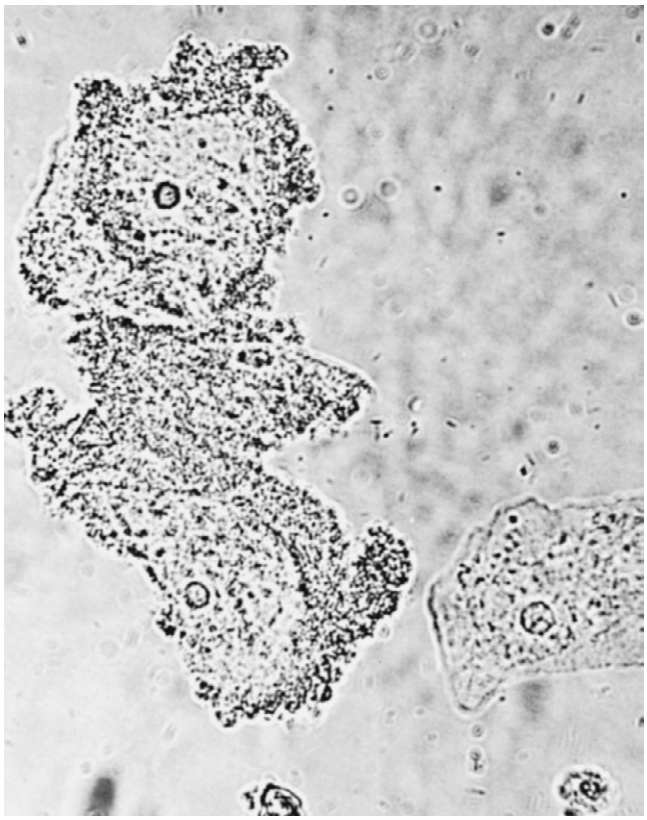

FIGURE 42-10 ■ The finding of bacteria clinging to the sides of a vaginal epithelial cell (clue cell) is significant in bacterial vaginosis. (Courtesy Herman L. Gardner, MD.)

Prepubertal

Bacterial vaginosis is defined poorly in premenarcheal girls. No published studies using the recommended diagnostic criteria exist. A few studies have used some of the criteria, however, in an attempt to examine bacterial vaginosis in premenarcheal girls. In a study examining STIs in girls aged 1 to 12 years who were evaluated for possible sexual abuse, 99 of the 245 girls with a vaginal discharge had an amine test and were examined for clue cells. Of the 99 girls, 7 (7%) had clue cells, a positive amine test, or both.[107] In a similar study, 22 of 51 girls with a history of sexual contact and a vaginal discharge had an amine test performed and were evaluated for clue cells; all of them were negative for both tests.[110] In the same study, in a second group of girls defined as being at risk for having had undetected previous sexual contact, 30 girls had a vaginal discharge and 10 had wet-mount preparations performed. One had a positive amine test and clue cells, and one had a positive amine test only. In both of these studies, the full criteria were not used, and only subgroups of girls with vaginal discharge were evaluated. In another study, 31 abused and 23 nonabused girls aged 2.5 to 13 years had vaginal washes performed along with amine tests and testing for clue cells.[88] The abused girls had an initial visit and a follow-up visit more than 7 days after the abuse occurred. The nonabused girls had only an initial evaluation. Of the 23 nonabused girls, 1 had a positive amine test with normal examination results and was asymptomatic. Similarly, 1 of the 31 abused girls had a positive amine test on the initial visit. On follow-up evaluation, clue cells and a positive amine test developed in 4 of the 31 abused girls and either clue cells or a positive amine test was noted in another 4 of the 31 girls. Either a new vaginal discharge or dysuria developed in 5 of these 8 girls. Of the 8 girls, 3 were postmenarcheal. Whether the testing itself could have been responsible for the positive results is unclear because the control group did not undergo the follow-up evaluation.[107]

In a study of premenarcheal girls older than 2 years with vulvovaginitis, none of the 50 girls or their age-matched controls had *G. vaginalis* isolated from vaginal specimens.[112] In a survey of vaginal flora in children without a vaginal discharge, *G. vaginalis* was isolated from 14 percent.[86] Prepubertal girls with a history of sexual abuse were more likely to have *G. vaginalis* isolated from vaginal specimens (15%) than were girls with no history of sexual abuse and either genitourinary complaints (4%) or no genitourinary complaints (4%).[15] In a study examining the vaginal flora of sexually abused and nonabused 3- to 10-year-old girls, 6 percent of abused versus 1 percent of nonabused girls had *G. vaginalis* in their vaginal secretions.[71] Although the prevalence of *G. vaginalis* and bacterial vaginosis is higher in sexually abused children than in nonabused children, their significance as a marker for sexual abuse is unclear. No data are available regarding the survival of *G. vaginalis* on fomites.

Until studies using the proper and complete criteria are done in young girls with and without a vaginal discharge, the prevalence of bacterial vaginosis will be unknown and the significance of bacterial vaginosis as a cause of vaginal discharge in premenarcheal girls will remain unclear. At this time, the presence of manifestations of bacterial vaginosis should prompt the health care provider to consider treatment of bacterial vaginosis. In addition, the possibility of sexual abuse should be contemplated because a diagnosis of bacterial vaginosis does not provide evidence of sexual abuse. Because bacterial cultures may be performed in the evaluation of a vaginal discharge in a premenarcheal girl and *G. vaginalis* may be identified, identification of *G. vaginalis* should not be considered evidence of sexual abuse or diagnostic of bacterial vaginosis (see Table 42-3).

Postpubertal

Bacterial vaginosis in adolescents is considered a sexually transmitted condition based on the occurrence of bacterial vaginosis with other STIs. Bacterial vaginosis also has been described in adolescent girls who are not sexually active.[31] Other risk factors are foreign bodies such as a forgotten tampon, vaginal douching,[103,224] no condom use, a new sexual partner, anal intercourse, unclean insertive sex toys, and an intrauterine device. In addition, the association among bacterial vaginosis and postpartum endometritis, premature rupture of membranes, and PID has implicated it as the cause for these gynecologic and obstetric complications.[35,226]

The primary complaint is an offensive fishy odor with moderately profuse, gray leukorrhea. A mild pruritus may be reported. Examination shows little or no vulvar or vaginal erythema. The vagina contains a thick, homogeneous, grayish-white discharge. The pH of vaginal secretions in bacterial vaginosis is 5.0 to 6.0.[35]

Diagnosis

Two methods are used to establish the diagnosis of bacterial vaginosis—Gram stain of vaginal discharge and clinical criteria,[35,58,226] with clinical criteria being used more commonly. A Gram stain of vaginal secretions is considered the most reliable diagnostic test for bacterial vaginosis. A predominance of gram-variable cocci and curved rods (anaerobes) and occasional long gram-positive rods (lactobacilli) is seen.[35] A saline wet mount of vaginal secretions is a rapid and helpful test for clue cells in a busy clinical setting (see Fig. 42-10). The Gram stain method is used to determine the relative concentrations of bacterial morphotypes and evaluate for the overgrowth of anaerobes. This method requires an examiner with expertise in evaluating specimens for bacterial vaginosis and is less practical than is the use of clinical criteria; thus, clinical criteria are used more widely.

The clinical criteria used for establishing the diagnosis of bacterial vaginosis in adolescents are the presence of any three of the four criteria[35,226]: (1) a homogeneous, gray-white malodorous discharge that smoothly coats the vaginal walls, (2) a pH of nonbloody vaginal secretions greater than 4.5, (3) a fishy odor caused by the release of amines when 10 percent potassium hydroxide is added to a nonbloody vaginal specimen (whiff test), and (4) the presence of clue cells in a nonbloody specimen. Microscopic examination of some of the discharge mixed with normal saline solution in a wet-mount preparation shows masses of desquamated vaginal epithelial cells and cellular debris. Clusters of bacteria adhere to the surface of many of the vaginal cells; these clue cells (see Fig. 42-10) are characteristic of the condition. Absence of erythrocytes and leukocytes in the discharge is another characteristic finding. Vaginal cultures for *G. vaginalis* and anaerobes are available; however, they are not useful clinically in children or adolescents and are not recommended.

Treatment

Numerous regimens for the treatment of bacterial vaginosis exist, but no specific recommendations are available for premenarcheal girls. Probably because bacterial vaginosis is diagnosed infrequently, clinical trials evaluating treatment of bacterial vaginosis in premenarcheal girls are lacking. The drugs recommended for use in young girls are those recommended for postmenarcheal women, with dosages based on the child's body weight. In small children (<45 kg), metronidazole can be given at 15 mg/kg/day divided two times per day for 7 days (maximum dose 1 g/day).[35,58]

The goal of therapy for symptomatic bacterial vaginosis in adolescents is to relieve vaginal symptoms and prevent an ecologic environment that predisposes to the development of PID. Treatment of asymptomatic bacterial vaginosis may be considered before performing a surgical abortion procedure to prevent postpartum PID. In most cases, bacterial vaginosis responds to metronidazole 500 mg orally twice per day for 7 days[35] or 2 percent clindamycin cream intravaginally every night for 7 days or 0.75 percent metronidazole gel intravaginally once per day for 5 days. Alternative regimens include clindamycin 300 mg orally twice per day for 7 days, or clindamycin ovules, 100 mg intravaginally once per day for 3 days. These regimens provide effective coverage of anaerobes and *G. vaginalis*. Bacterial vaginosis that occurs during pregnancy generally is treated during the first trimester with clindamycin cream. During the second and third trimesters of pregnancy, it can be treated with clindamycin cream or metronidazole gel. Treatment of the sexual partner has not proved to be beneficial.[35]

Infections of the Clitoris

Cellulitis with induration, edema, and erythema occasionally develops in the clitoral hood in the prepubertal and pubertal period.[58] Clitoral hood piercings can cause cellulitis in older adolescents. Staphylococci and streptococci are the most common etiologies. Oral antibiotics with efficacy against these organisms usually are effective. Warm soaks or sitz baths also may provide symptomatic relief.[58]

Clitoromegaly with erythema can occur with vulvovaginitis of any etiology but usually is associated with herpes simplex virus (HSV) infections.[54] Edematous enlargement of the clitoris and the labia without erythema has been reported in patients with Crohn disease.[146]

Urethritis

Urethritis is manifested clinically by dysuria, urinary urgency, or both and occurs particularly in sexually active postmenarcheal girls. Urethritis with internal dysuria can occur as a result of sexually transmitted infections, such as *T. vaginalis*, *N. gonorrhoeae*, and *C. trachomatis*, and has been implicated as an important cause of dysuria in sexually active girls.[200] Urethral infection by *C. trachomatis* may occur with or without cervical infection; this infection was associated with sterile pyuria in 50 percent of girls with acute-onset dysuria and frequency, and *C. trachomatis* was isolated in 31 percent of these cases.[200]

When a sexually active adolescent girl has internal dysuria, in addition to being tested for conventional uropathogens, she should be screened for common STIs, such as gonorrhea, chlamydia, and trichomonas infection.[50] Urinalysis and microscopy for the presence of leukocytes and bacteria should be done in these patients as well. For treatment of urethritis caused by sexually transmitted organisms, the sections in this chapter on trichomoniasis, gonorrhea, and chlamydial infections should be reviewed.

Bartholinitis and Bartholin Abscess

Infections of the Bartholin ducts occasionally occur in adolescent girls. The Bartholin glands are small, bean-shaped glands that lie on each side of the vaginal opening, behind the hymen. Each gland opens by means of a long single duct immediately external to the hymen.

Bartholinitis, or inflammation of the Bartholin ducts, causes pain, tenderness, and a linear rope-shaped swelling, best palpated by holding the vulvar mucosa and labia majora between the fingers. Purulent or mucoid exudate can be expressed occasionally from the Bartholin duct.

N. gonorrhoeae and *C. trachomatis* have been isolated almost a third of the time from ductal exudates in women with bartholinitis.[47,168] A Bartholin abscess does occur in sexually active adolescent girls. Risk factors for development of Bartholin abscess are similar to those for sexually transmitted infections.[3] Infection of a Bartholin cyst results in a markedly tender abscess (Fig. 42-11). The abscess can rupture spontaneously and drain foul-smelling, purulent material externally through the skin. Multiple organisms are isolated from Bartholin abscesses. An early study using percutaneous aspirates from abscesses showed predominantly anaerobes and facultative organisms. *N. gonorrhoeae* was isolated in 8 percent of cases, and gram-negative bacilli were isolated in 16 percent. Although genital Mycoplasmataceae organisms were isolated from the duct secretions, they were not isolated directly from abscesses.[130] *Porphyromonas asaccharolytica* (a black-pigmented, gram-negative anaerobe), *Salmonella panama* (after an attack of *Salmonella* enteritis), and *Mycobacterium tuberculosis* have been isolated from a Bartholin abscess.[45,51,55,104]

FIGURE 42–11 ■ Acute Bartholin duct abscess.

A Bartholin abscess should be incised and drained and not aspirated because it is likely to cause recurrent abscess formation. Incision plus drainage and primary suture of the abscess cavity along with administration of an antibiotic (clindamycin) has been found to lead to more rapid healing and decrease significantly the incidence of recurrent abscesses.[11] The cavity should be packed with sterile gauze. Alternatively, marsupialization or fistulization can be used to treat recurrent Bartholin abscesses.[219] A Word catheter inflated with water can be inserted into the cavity. Antibiotic coverage for anaerobes, *N. gonorrhoeae*, and *C. trachomatis* should be provided for at least 2 weeks, and a nonsteroidal medication is recommended for inflammation and pain. Frequent sitz baths help further with drainage and healing. Close follow-up during the first week is advised. The packing or the catheter may be removed after 4 days of antibiotics. Healing should be anticipated in 2 weeks.

VULVOVAGINAL LESIONS, ULCERATIONS, AND GRANULOMATOUS INFECTIONS

Vulvovaginal lesions, ulcerations, and granulomatous infections include genital warts, molluscum contagiosum, herpes genitalis, syphilis, chancroid, granuloma

inguinale, and tuberculosis. Human papillomavirus (HPV) and genital warts, molluscum contagiosum, and lymphogranuloma venereum will be addressed in detail in this chapter. All other conditions are described in detail in Chapters 130, 134, 143, and 157. The modes of transmission of all the previously mentioned infections and implications for child sexual abuse will also be discussed in this chapter (see Table 42-3).

Human Papillomavirus and Genital Warts

HPV is a small, slow-growing virus of the papovavirus group. HPV types 6 and 11 are responsible for 90 percent of genital warts (condyloma acuminata); HPV types 16, 18, and 31 are associated with premalignant and malignant cervical carcinoma in women, with HPV types 16 and 18 causing 70 percent of premalignant and malignant lesions.[115]

Prepubertal

Perinatal transmission of HPV from an infected mother to her infant is well documented. The incubation period after exposure to the virus may range from 1 to 20 months.[48] Data on the presence of HPV DNA in children beyond the neonatal period are inconsistent—1.2 to 27 percent in three different studies.[128,164,217] In addition, the relationship between the presence of HPV DNA and the ultimate development of disease in children is unclear. Because the exact incubation period for the development of genital lesions is unknown, perinatal transmission has been found to be the most likely cause of genital warts in almost 96 percent of patients younger than 3 years.[48] In children 3 years or older, a history of sexual abuse has been elicited in 27 to 90 percent with venereal warts.[38,97]

Genital warts are acquired by children as a result of close physical contact with an infected individual, by digital infection of the child's genitalia by an infected individual, or by sexual contact with an infected individual.[183] A history of genital warts in other members of the family, particularly the mother or older sisters who care for the child, sometimes may be elicited. Perinatal exposure, poor hygiene, and shared bathing have been suggested sources of infection.[203,204] HPV types 6, 11, 16, and 18 are the most common genital types detected in children. This finding has raised questions about warts in children resulting from sexual abuse. In many cases, however, the mode of transmission is unknown.[48] Based on failure to identify sexual abuse, a report from a dermatology clinic concluded that transmission of HPV possibly occurs by fomites.[38] No reports in the literature address survival of the virus on fomites.

Sexual abuse is the most common means of acquiring anogenital HPV infection and should be considered suspicious for sexual abuse and investigated and reported in all prepubertal children older than 3 years who are infected. In children younger than 3 years, although perinatal transmission is likely, sexual abuse should be suspected and investigated (see Table 42-3).[35]

As recommended by the CDC,[34] the possibility of sexual abuse should be considered strongly if no conclusive explanation for nonsexual transmission of an STI has been identified. When the only evidence of sexual abuse is the isolation of an organism or the detection of antibodies to a sexually transmitted agent, findings should be confirmed and implications should be considered carefully.

FIGURE 42-12 ■ Condylomata acuminata usually are single or scattered, small warts in premenarcheal children.

Genital warts (condyloma acuminata) in premenarcheal children may cover the entire vulva. Most often, however, warts in this population are single or scattered cauliflower-like lesions (Fig. 42-12). They have a predilection for the smooth, moist mucosa covering the vestibular mucosa, inner surfaces of the labia minora, and mucosa around the urethral meatus. Warts seldom become ulcerative, but those arising within the vagina may become necrotic and produce a bloody vaginal discharge. Although not tumors, genital warts should be considered in the differential diagnosis of vaginal neoplasms. HIV infection should be considered in infants and children with severe, extensive warts.[38,48,115]

Postpubertal

The prevalence of HPV in adolescents as detected by DNA isolation techniques is far higher than the prevalence of active disease. The cell-mediated or T-cell immune system seems to play an important role in whether the presence of virus results in clinically manifested disease. Cofactors of HPV infection in adolescents are herpes, cervicitis, and tobacco use. Immunosuppression from a variety of conditions, including renal transplantation, Hodgkin disease, and HIV infection, is associated with a greater likelihood of development of HPV disease.[115] With regard to the natural history of HPV infection, Moscicki and colleagues[142,143] found that high-grade squamous intraepithelial lesions (HSILs) were more likely to develop in individuals with persistent

FIGURE 42-13 ■ Condylomata acuminata may form large masses covering the vulva in postmenarcheal patients.

positive tests showing oncogenic HPV types. During the course of a 2-year period, 70 percent of cases showed regression. Daily cigarette smoking was strongly linked to the development of low-grade squamous intraepithelial lesions (LSILs).[142] Regression was more likely in young women with LSIL than in those with HSIL.

In postmenarcheal girls, genital warts usually form discrete, sessile, vegetative, wartlike growths covered with folded grayish-pink epithelium. They are found most frequently on the smooth mucosa of the vulvar vestibule. Vaginal and cervical lesions commonly accompany the lesions on the vulva. Usually, they are accompanied by more or less vaginal discharge. Most often, associated pruritus and secondary infection are present. Contact lesions frequently appear on contiguous surfaces. Huge condylomatous masses (Fig. 42-13) that completely hide the introitus can develop in adolescents; if not treated, these huge growths may invade the rectum.

Diagnosis

Diagnosis is usually made clinically. HPV testing and biopsy of warts are not recommended in children and adolescents. A biopsy may be considered if genital warts appear necrotic or the morphologic appearance is not classic for warts.

Treatment

The goal of treatment is removal of warts and amelioration of symptoms, not eradication of HPV. No therapy has been shown to eradicate HPV. When only a few lesions are present, they can be treated in the outpatient setting with 85 percent trichloracetic acid. In infants and children with extensive lesions, electrocautery, electrocoagulation, or laser treatment, general anesthesia may be needed and may result in deep scarring and distortion of the vulva. Older children and young adolescents usually tolerate cryotherapy without general anesthesia if they know that some tingling or burning sensation is associated with it. Liquid nitrogen may be used in the same manner as solid carbon dioxide. Reports in the international literature demonstrate successful treatment of extensive warts in children using imiquimod 5 percent cream.[115,133]

The therapeutic methods available are 22 to 94 percent effective in clearing exophytic genital warts, but recurrence rates are high, at least 25 percent within 3 months. Treatment seems to be more successful for genital warts that are small and present for less than 1 year.[35] When a few lesions are present on the vulvar and labial areas, they can be treated in the office setting with 10 to 25 percent podophyllin resin or a solution of 85 percent trichloroacetic acid. Urethral, anal, vaginal, and cervical lesions should not be treated with podophyllin. The medication is applied to the wart only (not to the surrounding skin), and treatment is repeated once weekly until the lesions have disappeared (usually 3 to 4 weeks). Four hours after podophyllin has been applied, the treated area should be washed off with soap and water. Self-application of 0.5 percent podofilox gel may be considered in older nonpregnant adolescents who are comfortable using this approach and can understand the treatment regimen so as to avoid dermatologic side effects.

Imiquimod 5 percent cream also is recommended for the treatment of warts in patients older than 18 years.[35] This medication is self-applied to the lesions, three times per week for 16 weeks. Laser treatment or cryocautery is recommended if the lesions do not respond to chemical cautery or if they progressively increase in size. Large perianal warts may need to be removed surgically if cryotherapy does not work. Alternative treatments for adolescents are topical 5-fluorouracil in 5 percent creams and intralesional interferon. 5-Fluorouracil is preferable for vaginal and intraurethral warts and seems to be more effective than is the laser in treating exophytic warts in the vagina.[35,48]

The first endocervical Pap smear to screen for HPV-related changes is recommended at age 21 years.[9,176] The quadrivalent (types 6, 11, 16, and 18) and bivalent (types 16, 18) HPV vaccines are approved by the U.S. Food and Drug Administration, the former to prevent genital warts and cervical cancer and the latter to prevent cervical cancer.[135]

Molluscum Contagiosum

Molluscum contagiosum is a viral infection of the skin caused by a DNA pox virus characterized by small, discrete, translucent, grayish-pink, umbilicated, wartlike papules that sometimes are surrounded by a narrow ring of erythema. The lesions, which are asymptomatic, usually are less than 5 mm in diameter and may be missed by the patient and the examiner. The disease is transmitted by close physical contact, including sexual activity,

and is encountered most often in postmenarcheal patients on the inner surfaces of the thighs, the perineum, and the lower part of the abdomen. The average incubation period is 2 to 7 weeks and can be as long as 6 months. Pediatricians frequently encounter molluscum contagiosum on the nongenital skin of children. It can be contracted from contaminated towels, bedding, and garments. Lesions of molluscum contagiosum on the lower part of the abdomen, pubis, thighs, or perineum of a child are tacit evidence of sexual contact.[39,132]

The appearance of the lesions usually is sufficient to establish the diagnosis. It can be confirmed by finding large, intracytoplasmic inclusion bodies in a smear or biopsy specimen from a lesion.

Lesions may go away on their own and usually last 6 to 8 weeks. They do not recur. A variety of treatment approaches are available if the lesions continue to spread. Curettage is the most efficacious treatment, with a low rate of side effects; however, the procedure requires anesthesia and is time-consuming. Cryotherapy gives good results. Topical imiquimod holds promise, but an optimal treatment schedule has not been determined.[35,39]

Ulcerations and Granulomatous Infections

Sexually transmitted genital ulcerative and granulomatous infections occur throughout the world but are found most frequently in tropical countries. Genital ulcers are a common finding on evaluation of adolescent and adult patients with genital symptoms. They are less common findings in young children. Ulcers usually are secondary lesions that result from the breakdown of vesicles, papules, or pustules. By the time that many patients with genital infections seek medical attention for their symptoms, the primary lesion has proceeded to ulceration.[193] Microbial causes vary by geographic region and socioeconomic status: HSV is the most common cause in Western Europe and North America, whereas chancroid is the most common in the tropics; in the United States, syphilis and chancroid are more common occurrences in urban minority groups, whereas HSV is found more commonly in more affluent groups. Complications of sexually transmitted genital ulcerative diseases also occur more commonly in developing countries and often are the reason for seeking medical care.[145]

HSV infection, syphilis, chancroid, lymphogranuloma venereum, granuloma inguinale, and tuberculosis all may have genital ulcers as a major clinical finding (Table 42-4). Although each of these diseases has a characteristic lesion and course, considerable overlap exists, so a diagnosis based on the history and physical appearance alone often is inaccurate. Herpetic ulcers, contrary to classic manifestations, can be painless, and syphilis chancres can be painful at times (see Chapters 143 and 157). Secondary infection of an ulcerated area may cause pain in lesions that characteristically are painless. In addition, more than one STI may be present in at least 3 to 10 percent of patients with genital ulcers.

Genital ulcers also may result from infestation, fixed drug eruption, mechanical or chemical trauma, autoimmune processes (e.g., Behçet syndrome and Crohn disease[146]), and neoplasia. The presence of ulcers in sites other than the genital regions or oropharynx suggests a noninfectious etiology. The vulvar lesions of Behçet syndrome appear as destructive, deep, relatively painless ulcerations that, on recurrence, can result in scarring and distortion with progressive loss of vulvar tissue.[119,165]

In the United States, most patients with genital ulcers have genital herpes, syphilis, chancroid, or a combination thereof. Empirical treatment often must be given before diagnostic test results are available, and laboratory confirmation of a specific diagnosis is lacking in at least a quarter of patients with genital ulcer disease. Treatment of syphilis and chancroid should be considered in such circumstances, especially in geographic regions where chancroid morbidity is notable (see later discussion).[34,154]

Genital ulcers and granulomatous infections of any etiology, but especially those caused by herpes, syphilis, chancroid, and granuloma inguinale, are associated with an increased risk for acquiring HIV infection. Serologic testing for HIV infection should be considered in the management of patients with genital ulcers.[35] Improved treatment of STIs can affect the rate of HIV seroconversion in a population.[81]

Perinatal transmission of HSV types 1 and 2 in the form of stomatitis occurs in infants. HSV infection of the genitalia rarely occurs in children.[91,116] The presence of genital herpes lesions in a child or any disease that is known to be sexually transmitted in an adult should raise a question about whether the child has been subjected to some type of sexual molestation. HSV types 1 and 2 have been isolated in the genital area in children alleging sexual abuse.[72,107] The mode of acquisition of the infection is not always known, but case reports describe the possibility of autoinoculation from oral lesions, physical contact by a mother's infected finger, and sexual abuse.[116] No studies have reported the coexistence of HSV genital infection in household members and infected children. HSV has been known to survive for 2 hours on latex gloves and toilet seats, 24 hours on a speculum, and 72 hours on gauze.[129] However, transmission of HSV from fomites requires direct contact of viable virus with either a mucous membrane or a break in the skin, rendering fomite transmission unlikely. In conclusion, a child with genital herpes infection should be considered suspicious and evaluated for sexual abuse, and the case should be reported to the authorities (see Table 42-3).[35]

Syphilis infections not found to be acquired congenitally should be considered sexually transmitted. Sexually acquired infection is a strong possibility in all prepubertal children with syphilis. The presence of syphilis should be considered diagnostic of sexual abuse, and an investigation must be pursued (see Table 42-3). In three studies, syphilis has been identified in 0, 0.3, and 5 percent of cases of alleged sexual abuse.[49,76,106] Syphilitic lesions and positive serologic results have been detected in alleged sexual abusers of children with syphilis.[1] No data are available on the survival of *Treponema pallidum* on fomites.

Lymphogranuloma venereum will be addressed in this chapter. The remaining listed infectious etiologies of genital ulcerative and granulomatous infections, including herpes, syphilis, chancroid, and granuloma inguinale,

TABLE 42-4 **Diagnostic Features of Genital Ulcerations Caused by Sexually Transmitted Diseases**

Feature	Primary Syphilis	Genital Herpes	Chancroid	Lymphogranuloma Venereum	Granuloma Inguinale
Incubation period	9-90 days; avg, 2-4 wk	2-7 days	1-35 days; avg, 3-7 days	3 days to 3 wk; avg, 10-14 days	Precise data unavailable; probably a few days to several months
No. lesions	Usually one; may be multiple	Multiple; may coalesce, more with primary episodes than with recurrences	Usually one to three, may be multiple	Usually single	Single or multiple
Description of genital ulcers	Sharply demarcated, round or oval ulcer with slightly elevated edges; may be irregular, symmetric "kissing chancre"	Small, superficial, grouped vesicles, erosions, or both; lesions may coalesce and form bullae or large areas of ulceration; lesions have irregular borders	Superficial, shallow, sharply demarcated ulcer; irregular, ragged, undermined edge; a few millimeters to 2 cm in diameter	Papule, pustule, vesicle, or ulcer discrete and transient; frequently overlooked	Sharply defined, irregular ulcerations or hypertrophic, verrucous, necrotic, or cicatricial granulomata
Base	Red, smooth, and shiny or crusty; oozing serous exudate when squeezed	Bright red and smooth	Rough, uneven, yellow to gray	Variable	Usually friable, rough, beefy granulations; can be necrotic, verrucous, or cicatricial
Induration	Firm; does not change shape with pressure	None	Soft; changes shape with pressure	None	Firm granulation tissue
Pain	Painless; may become tender if secondarily infected	Common; more prominent with initial infection than with recurrences	Common	Variable	Rare
Inguinal lymphadenopathy	Unilateral or bilateral, firm, movable, and nontender; does not suppurate	Usually bilateral, firm, and tender; more common in primary episodes than in recurrences	Unilateral; bilateral rarely occurs; overlying erythema; matted, fixed, and tender; suppuration may occur	Unilateral or bilateral; initially movable, firm, and tender; later indolent; fixed and matted; "sign of groove" may suppurate; fistulas	Pseudobuboes; subcutaneous perilymphatic granulomatous lesions that produce inguinal swellings
Constitutional symptoms	Rare	Common in primary episode; less likely in recurrences	Rare	Frequent	Rare
Course of untreated disease	Slowly (2-6 wk) resolves to latency	Recurrence is the rule	May progress to erosive lesions	Local lesions heal; systemic disease may progress; disfiguring; late complications	Worsens slowly
Diagnostic tests	*Treponema pallidum:* Darkfield examination, direct immunofluorescence, RPR, TPPA, FTA-ABS, VDRL	*Herpes simplex types 1 and 2:* Culture, PCR, direct immunofluorescence, Tzanck smear, electron microscopy, direct immunoperoxidase staining, serology	*Haemophilus ducreyi:* Culture, biopsy (rarely used), Gram-stained smears have low specificity	*Chlamydia trachomatis LGV 1, 2, 3:* Complement fixation, isolation of microorganism by culture	*Klebsiella granulomatis:* Donovan bodies in tissue smears; biopsy

Modified from Mroczkowski TF, Martin DH. Genital ulcer disease. *Dermatol Clin* 1994;12:753–764.[145]

avg, Average, *FTA-ABS,* fluorescent treponemal antibody absorption test; *RPR,* rapid plasma reagin; *TPPA,* treponema pallidum particle agglutination; *VDRL,* Venereal Disease Research Laboratory.

are described in more detail in Chapters 130, 134, 143, and 157.

Lymphogranuloma Venereum

Lymphogranuloma venereum is caused by *C. trachomatis*, subtypes L1 to L3. It is characterized by indolent inflammatory infiltration, granulomatous ulceration, abscess formation, and fibrotic cicatrization of the inguinal, perineal, and rectal lymphatics. It occurs more often in tropical than temperate climates.

Adolescents acquire lymphogranuloma venereum through sexual activity. Lymphogranuloma venereum has been reported in children[14,77,220] and always should raise suspicion for child sexual abuse. Nonsexual transmission by accidental inoculation of infected material from family members via handling of garments or towels that have been contaminated by drainage from ulcerative lesions or buboes of other household members has been postulated. Some evidence suggests that transplacental or perinatal transmission of the lymphogranuloma venereum serovars of *C. trachomatis* can occur.[77]

The primary lesion, a small papule or superficial and relatively asymptomatic ulcer (Fig. 42-14), seldom is seen in either children or older patients. A prodromal episode of fever, malaise, and joint pain accompanied by leukocytosis and anemia may precede the local signs. These symptoms often are mild and not diagnostically significant.

The most common manifestation is inguinal or femoral lymphadenopathy that is usually unilateral. When untreated, the adenitis may progress to abscess formation (buboes), followed by rupture, with the development of draining sinuses. Spontaneous regression sometimes occurs. Rectal exposure can lead to proctocolitis that may be associated with anal pain, mucoid or hemorrhagic rectal discharge, constipation, or tenesmus. Fever also can occur. Untreated proctocolitis can progress to colorectal fistulas and strictures over time. Reactive manifestations, as with other forms of *C. trachomatis* infection, can occur and include arthritis, usually of the knees, and erythema nodosum.[77]

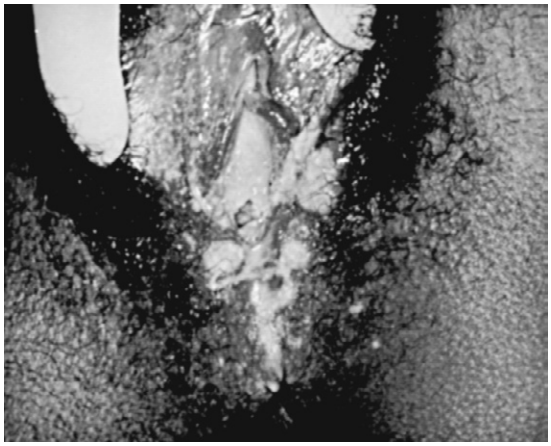

FIGURE 42-14 ■ Early lesions of lymphogranuloma venereum in the form of herpetic-like ulcers in an adolescent. The diagnosis was confirmed serologically.

Diagnosis can be made by culture, direct immunofluorescence, or nucleic acid tests of genital or lymph node specimens for *C. trachomatis*. Swabs of ulcerative lesions or aspirates of buboes may be used. Nucleic acid amplification tests are not FDA-approved for rectal specimens though some laboratories may have performed sufficient validation studies to offer these. Serum complement fixation titers greater than 1:64 can be used to support the diagnosis of lymphogranuloma venereum in appropriate clinical contexts.

Lymphogranuloma venereum may coexist with syphilis, and false-positive Venereal Disease Research Laboratory test results have been reported. Specific tests for antitreponemal antibodies should be obtained to confirm coinfection with syphilis when nontreponemal tests are positive. The disease is differentiated from other granulomatous and ulcerative disorders by specific tests for each, biopsy, and clinical appearance of the lesions (see Table 42-3).

The preferred treatment of lymphogranuloma venereum is doxycycline 100 mg orally twice per day for 21 days.[35] The alternative regimen is erythromycin base 500 mg orally four times per day for 21 days. Azithromycin 1 g orally once per week for 3 weeks is probably effective, but clinical data are lacking. A macrolide-based regimen is preferred for children younger than 8 years of age. Treatment can prevent progression of tissue damage but may not reverse scarring that has already occurred. Aspiration or incision and drainage of buboes may be required in some cases. Sexual contacts of patients with lymphogranuloma venereum within the 60 days before onset of the patient's symptoms should be evaluated and treated with a chlamydia regimen.[35]

Cervicitis

Prepubertal

The cervix is not involved when a prepubertal child has vaginitis because most vaginal infections affect only the distal half of the vagina in children; the exception is gonococcal vaginitis, which in addition usually involves the squamous epithelium over the external cervix. Cervicitis also may occur when a vaginal foreign body is present. Endocervicitis is an unusual finding in premenarcheal girls because the endocervical glands and mucosa are developed poorly before menarche, providing a poor environment for invading organisms.[59,226]

Postpubertal

The structure of the cervix during the reproductive years renders it vulnerable to infections induced by numerous factors. The long, narrow, deeply pocketed cervical canal, which is lined by open cryptic glands bathed in alkaline secretion and washed periodically by menstrual blood, is an excellent nidus for the growth of bacteria. Pathogenic bacteria in the vagina find ready access to the cervical canal. The use of oral contraceptive pills promotes cervical ectopy, increasing the vulnerability of endocervical cells to chlamydial infection.[101,102,226]

Early recognition and aggressive treatment of cervicitis in sexually active adolescents are important to prevent serious complications, including PID and tubo-ovarian abscess. Some confusion tends to occur, however, with regard to differentiating normal ectopic columnar epithelium on the exocervix (ectopy) from cervicitis. Ectopy is not an abnormal finding. When the squamocolumnar junction is exposed on the exocervix, it is called *ectopy*. It appears bright shiny red, in contrast to the dull pearly pink appearance of the exocervix. This area does not bleed easily when touched with a swab. During adolescence, the normal cervix may exhibit no ectopy, a small area of ectopy, or sometimes 50 percent ectopy. When the ectopy appears edematous, raised, and friable (often with marked bleeding when touched lightly with a swab), cervicitis should be suspected.[101,226]

Cervicitis primarily is endocervicitis most commonly associated with *C. trachomatis* and *N. gonorrhoeae*. However, the etiology in most cases is not determined and could be from *Mycoplasma genitalium*, *G. vaginalis*, group B streptococci, and *T. vaginalis*. Because of the high prevalence of coexisting infections of the cervix, associating any one organism with the clinical signs and symptoms of cervicitis often is difficult.[101,173,185]

Cervicitis often is asymptomatic, but it should be clinically suspected if an adolescent reports a vaginal discharge and bleeding, especially after having sexual intercourse. Criteria for a clinical diagnosis of mucopurulent cervicitis include the presence of mucopurulent secretion from the endocervix, erythema of the cervix, friable ectopy, and bleeding from the cervix.[28] The mucopurulent secretion in chlamydial cervicitis is tenacious mucoid material mixed with yellow exudate and is difficult to remove from the endocervix. In contrast a profuse, yellowish-green acrid discharge is present in gonococcal cervicitis. Cervical erosion ulcerations can occur in sexually active adolescents and can be caused by HSV. Rarer causes are the primary lesion of syphilis, tuberculosis, granuloma inguinale, lymphogranuloma venereum, chancroid, schistosomiasis, and actinomycosis.

Diagnosis

Tests for chlamydial and gonococcal infection should be performed in all sexually active adolescents. Nucleic acid amplification tests are considered the most sensitive and specific tests today, and testing of urine and self-obtained vaginal specimens has revolutionized screening and diagnosis. The reliability of amplification tests such as polymerase chain reaction, strand displacement amplification, and transcription-mediated amplification in detecting chlamydia and gonorrhea seems to be equivalent for vaginal, cervical, and urine specimens as long as the urine collected is a first-catch specimen; the sensitivities range from 87 to 99 percent and specificity from 97 to 100 percent.[18,178,180,190]

Other tests, including culture, direct fluorescent antibody tests, enzyme immunoassay, nucleic acid hybridization tests, enhanced optical immunoassays, and nucleic acid amplification tests, continue to be available today to diagnose *C. trachomatis* infection. The regular culture and tissue culture method was considered the gold standard for both gonorrhea and chlamydia[179] but because of the high cost of this technique, it is not used widely for adolescents. In some large-volume, community-based clinics, the DNA hybridization assay or DNA probe (Gen-Probe) and enzyme immunoassay (Abbot, Wampole, Kodak, Gen-Probe) are still used for gonorrhea and chlamydia.[122,181,190,195]

Commercial multiplex tests are available for *M. genitalium*, *U. urealyticum*, *T. vaginalis*, and *G. vaginalis*. However, the utility of testing for other organisms in adolescents is questioned, especially in clinical settings in which microscopy is readily available. However, in settings without microscopy, using commercial tests for *T. vaginalis* and *G. vaginalis* may be of value.

Although the reliability of detecting gram-negative intracellular diplococci on a Gram stain of cervical secretions is low, this test can be useful in areas where more sophisticated tests are unavailable. The presence of at least eight pairs of gram-negative intracellular diplococci in at least three polymorphonuclear cells strongly suggests gonococcal cervicitis.

Treatment

The same guidelines for the treatment of gonococcal and chlamydial cervicitis are used for the treatment of presumptive cervicitis in nonpregnant adolescents. Azithromycin 1 g orally in a single dose or doxycycline 100 mg once per day for 7 days is recommended for presumptive *C. trachomatis*, *M. genitalium*, and *U. urealyticum* cervicitis.[35] Current treatment of gonococcal infection is influenced by the emergence of antibiotic-resistant strains, including penicillinase-producing *N. gonorrhoeae*, fluoroquinolone-resistant strains, tetracycline-resistant strains, and chromosomally resistant strains.[35] The high frequency of chlamydial infection in individuals with gonorrhea (45% in certain populations) and the serious complications resulting from untreated gonorrhea and chlamydial infections also have influenced the treatment approach. Treatment options include intramuscular ceftriaxone 250 mg in a single dose plus azithromycin 1 g orally in a single dose, or doxycycline 100 mg orally twice per day for 7 days.[35]

In the case of penicillin allergy, cephalosporins are not contraindicated unless the patient has a history of a severe reaction (e.g., anaphylaxis, Stevens-Johnson syndrome, and toxic epidermal necrolysis). Spectinomycin is an alternative but is unavailable in the United States.[35] Azithromycin 2 g is effective to treat gonococcal cervicitis; however, because of emerging resistance, its use should be limited.[35] Pregnant adolescent girls or women should not be treated with doxycycline. If pharyngeal or rectal gonorrhea is suspected, the recommended treatment is intramuscular ceftriaxone 250 mg. When *T. vaginalis* vaginitis is diagnosed or HSV is suspected strongly, the appropriate treatment for these infections should be given (see discussions on trichomoniasis and genital herpes). Currently no CDC consensus exists on the treatment of asymptomatic individuals with positive tests for *M. genitalium* and *U. urealyticum*.[34]

Integral to treating the patient is notification, examination, and expedited treatment of the patient's sexual partners if gonococcal or chlamydial infection, or both, is confirmed. Direct notification by the patient should be encouraged, and, based on state laws, a prescription for partner therapy can be given. Written information should be provided with names of diseases and medication side effects to assist with this process. When tests are positive for gonorrhea or chlamydial infection, retesting for these infections is recommended—in 3 weeks if treated with erythromycin or if symptoms persist and in 3 months if treated with other regimens to detect reinfection from an untreated or new partner.[35]

Chlamydia

Chlamydia infections are the most frequently reported STIs in the United States, and the highest rates are reported in adolescents 15 to 19 years old.[34] Prevalence rates of chlamydial cervicitis in adolescents range from 8 to 25 percent in urban clinics located in hospital, community, family planning, and juvenile detention centers. It is three to four times more common than gonococcal cervicitis.[34] *C. trachomatis* causes cervicitis by infecting the columnar and transitional epithelium of the cervix. Cervical ectopy seems to be a predisposing factor for acquisition of *C. trachomatis* infection.[13] *C. trachomatis* cervicitis is predominantly an asymptomatic disease in adolescent girls.[36] A clinical diagnosis is made when friable ectopy with a mucopurulent cervical discharge (mucopus) is noted. Chlamydial cervicitis is suspected when a Gram stain of an adequate endocervical smear shows more than 5 to 10 polymorphonuclear cells per oil immersion field in the absence of gram-negative intracellular diplococci.[28,144]

Treatment of chlamydial cervicitis was discussed in the earlier section on cervicitis.

Gonorrhea

The highest rates of gonorrhea infections are reported in adolescents 15 to 19 years old.[34] The risk for acquiring infection varies with the population. Adolescents seen in private practices in the suburbs have a significantly lower rate of gonococcal cervicitis than that noted in adolescents seen in large outpatient hospital clinics or community clinics serving inner-city populations. The prevalence rate of gonorrhea in adolescent girls in urban hospital settings ranges from 3 to 12 percent in hospital, community, family planning, and juvenile detention centers.[34] Anal gonorrhea usually is secondary to discharge from gonococcal cervicitis infecting the anus. Primary anal gonorrhea as a result of anal intercourse should be suspected in a sexually active adolescent with anal discomfort. In addition, gonococcal infection should be considered in the differential diagnosis of pharyngitis in sexually active adolescents. Gonococcal endocarditis, arthritis, and dermal abscesses occur, but they are beyond the scope of this chapter.

Gonococcal cervicitis may be symptomatic or asymptomatic. Although gonococcal cervicitis is reported to be predominantly an asymptomatic condition in girls and women, many patients, after careful questioning, are found to have symptoms. The discharge is profuse and prevalent. On examination, the vulvar tissues may be inflamed and edematous. Discharge also may be seen exuding out of the urethra and paraurethral ducts in severe cases. On speculum examination, the patient has a normal-appearing cervix or the cervix appears erythematous and friable, with a foul-smelling purulent discharge draining from the cervical os.

Treatment of gonococcal cervicitis was discussed in the earlier section on cervicitis.

UPPER GENITAL TRACT INFECTIONS

Pelvic Inflammatory Disease

PID is defined as an acute clinical syndrome attributed to the ascent of microorganisms from the vagina and endocervix to the endometrium, fallopian tubes, or contiguous structures that result in pelvic and generalized peritonitis. The use of terms specifically describing the anatomic sites involved is preferable (e.g., endometritis, salpingitis, salpingo-oophoritis, tubo-ovarian abscess).

PID is an extremely rare finding in prepubertal girls and often is undiagnosed until advanced infection occurs.[27,53] With the exception of gonorrhea and the inflammation caused by a foreign body, most vulvar and vaginal infections do not involve the upper third of the vagina and do not approach the cervix of premenarcheal patients. The prepubertal cervix and endometrium apparently are barriers rather than passageways for bacteria causing all types of vulvovaginitis in children.

When intrapelvic infection has been reported in prepubertal girls, it usually has been part of either generalized primary peritonitis or peritonitis secondary to a ruptured appendix or some other intra-abdominal infection.[58] Pelvic infection that is part of an intra-abdominal infection characteristically affects the surfaces of the uterine tubes, uterus, and ovaries and produces perisalpingitis and periovaritis; periappendicitis also is present even if the infection did not begin as appendicitis. An ascending infection from the lower genital tract, such as that caused by gonorrhea, involves the tubal mucosa and produces endosalpingitis and pyosalpingitis. Gonococcal pelvic infection has been reported after sexual abuse has occurred. *S. pneumoniae* serotypes 1 and 2 and *E. coli* also have been reported in pubertal girls with salpingitis and peritonitis and tubo-ovarian abscess.[27]

PID in the postpubertal period occurs primarily in sexually active adolescents at risk for STIs.[60,190] Salpingitis has been reported in virgins, and, although the etiology is unknown, the organisms are thought to spread hematogenously, lymphatically, or transmurally from intestines or ascending infection from the vagina.[53] National epidemiologic data on PID specific to the adolescent age group are not available. However, the CDC reported a significant decline in the number of hospitalizations and initial visits to physician offices for PID among women 15 to 44 years of age between 2000 to 2009/2010.[34] This decline has been attributed to aggressive screening for chlamydia and gonorrhea infections in sexually active

adolescents in a variety of health care settings that serve urban sexually active adolescents.[34]

Reasons for the development of PID in adolescents are physiologic and social and include sexual activity and multiple sexual partners. Cervical mucus is less viscous during menses and at midcycle, rendering it more permeable to ascending infection. In vitro experiments show that *N. gonorrhoeae*, *C. trachomatis*, *U. urealyticum*, and other aerobic and anaerobic agents can adhere to spermatozoa and migrate with them.[212] Whether this event can occur in vivo is unknown. Most organisms found in nongonococcal and nonchlamydial PID also are found in bacterial vaginosis, suggesting that bacterial vaginosis may be a predisposing or a precipitating factor for the development of PID. In addition, researchers have suggested that *T. vaginalis* can act as a vector for transporting bacteria.[117] Another possible factor is upward transport of bacteria from orgasmic myometrial contractions.[155] Finally vaginal douching has been reported to be a risk factor in promoting ascending infection.[153,155,224]

Oral contraceptive pills are used commonly by adolescents and may have a protective or facilitating risk factor for PID. Laparoscopic studies also have shown that women with PID who were using oral contraceptive pills have significantly milder degrees of fallopian tube inflammation than do women who do not use the pills. This finding suggests that the oral contraceptive pill may reduce potential tubal damage. Other studies report, however, that by promoting cervical ectopy, oral contraceptives are a potential risk factor for acquiring chlamydial PID.[186,209,225] In contrast, compared with other methods of contraception, women using depot medroxyprogesterone acetate (Depo-Provera) had a significantly decreased risk for developing PID.[225] Risk for acquiring PID with the intrauterine device seems to be related to the individual's background risk for acquiring an STI and a direct complication of the device.[190]

Women who have had one episode of PID have a 20 to 25 percent chance of having subsequent ones. Reasons for this susceptibility may be reinfection from untreated sexual partners, an inadequately treated first infection, or increased susceptibility of the tubal epithelium to infection.[60,155]

Endometritis

Infections of the endometrium in postmenarcheal girls and women are as rare as previously thought. The gonococcus, on its way upward to the uterine tubes, produces a fleeting asymptomatic infection of the endometrium, or the symptoms produced are overshadowed by those of the vulvar and cervical infections. Evidence also suggests that endometritis occurs in 40 percent of patients with asymptomatic endocervical chlamydial infection.[114] It also is called *subclinical PID*, and repeated episodes have been linked to infertility.[114,221] The role of HIV infection in the development of subclinical PID is unclear. An increased prevalence of endometritis in HIV-infected women compared with uninfected women has been noted, and altered immune function might contribute to difficulty clearing endometritis in these cases.[29]

Symptoms specific to endometritis are uncommon. It is commonly an asymptomatic condition. Symptoms include recurrent intermittent or acute suprapubic pain and tenderness with vaginal bleeding or spotting. On bimanual examination, the uterus is tender, and cervical motion tenderness may or may not be present. Endometritis in adolescent girls and young women also has been associated with postabortive and puerperal endometritis. Poor compliance with prophylactic antibiotics places an adolescent at an increased risk for development of endometritis after having an abortion. Endometrial tuberculosis is a rare occurrence in the United States and is encountered most often in patients with pulmonary tuberculosis. This entity needs to be considered in HIV-infected girls and women and in geographic areas and regions where tuberculosis is endemic. In a study from a province in Iran, tuberculous endometritis was detected in 72 percent of genital tuberculosis cases in women.[151] The disease may not manifest for years after initial seeding, and the infection is thought to reach the uterus via the gastrointestinal tract through hematogenous seeding and by lymphatic spread. It is not acquired as a result of an ascending infection or through coitus with an infected man. The symptoms of endometrial tuberculosis vary from none to amenorrhea, pelvic pain, dysmenorrhea, abnormal uterine bleeding, and tuberculosis. Often, the patient has a history of healed or active pulmonary disease. Overall, 60 percent of patients with pelvic tuberculosis have tuberculous endometritis.[92]

Endometrial tuberculosis is diagnosed by endometrial biopsy and demonstration of acid-fast *M. tuberculosis* in cultures of curettage material or menstrual blood. Menstrual fluid has been reported to be culture-positive more frequently than are biopsy specimens.[92] Endometrial tuberculosis and the management of tuberculosis are described further in Chapter 96.

Salpingitis

The pathogenesis of salpingitis has been studied best with *N. gonorrhoeae* and *C. trachomatis*. In the fallopian tube, gonococci attach to nonciliated epithelial cells and induce sloughing of ciliated epithelial cells into the lumen.[155,207] Gonococci also enter the subepithelial space, where a local inflammatory response, predominantly polymorphonuclear leukocytic infiltrate and anaerobic bacteria, is produced and may reach the bloodstream. A purulent exudate is produced within the tube and may cause pelvic peritonitis. Chlamydial infection produces a similar picture except that it causes a predominantly lymphocytic infiltrate in the submucosa.[155,157,207]

Salpingitis also is caused by several other microbial agents that have been isolated directly from the fallopian tubes. The organisms most commonly recovered from the upper tract in salpingitis are mixed anaerobes (25% to 84%), followed by *N. gonorrhoeae* (25% to 40%) and *C. trachomatis* (25% to 40%). Mixed aerobic and anaerobic infections, including *Bacteroides* and *Peptostreptococcus* spp., account for 25 to 60 percent of cases. These mixed infections occur more frequently in girls and women with severe, chronic, and recurrent PID. PID develops in approximately 10 to 17 percent of girls and women with

endocervical *N. gonorrhoeae* and in 10 to 30 percent with endocervical *C. trachomatis*. At first, researchers thought that *N. gonorrhoeae* initiated the infection and that superinfection with anaerobes followed. They now realize that apparently anaerobes and aerobes can initiate PID without *C. trachomatis* or *N. gonorrhoeae*.[155,190,223]

Differentiating salpingitis caused by different microbiologic organisms is difficult. *N. gonorrhoeae* has been identified most frequently within the initial 24 hours of development of symptoms. Beyond 48 hours, the most frequent isolates are anaerobes. Gonococcal or chlamydial salpingitis seems to occur most often within 1 week of menstruation.[208] The clinical presentation varies from asymptomatic to severe disease. The severity of infection depends on duration of symptoms and the etiologic agent. Chlamydial PID tends to be less symptomatic than infection from *N. gonorrhoeae*.

Diagnosis

The classic manifestation of acute PID is lower abdominal pain, which usually is bilateral and continuous and may worsen with movement. After the onset of abdominal pain, fever, nausea, and vomiting develop. The temperature may reach 39° to 39.5° C (102° to 103° F). A chill seldom precedes the fever. Other common initial symptoms include vaginal discharge, irregular vaginal bleeding, and urinary symptoms.

On physical examination, the patient usually looks sick and uncomfortable. Abdominal examination reveals a markedly tender and often tense lower part of the abdomen. Rebound tenderness indicates generalized peritonitis. The genital examination may show a purulent vaginal discharge in the vaginal vault. Even gentle bimanual rectovaginal abdominal palpation causes great distress. Attempted mobilization of the cervix is extremely painful. The uterus is tense and tender. The adnexa may not be outlined because of discomfort produced by the examination. Palpation of the adnexa unilaterally or bilaterally may be exceptionally painful. An adnexal swelling may be palpated, but this finding is unreliable in diagnosing an adnexal mass. In a less acutely tender patient, the examination may reveal a thickened, tender tube.

Common laboratory findings in patients with PID include a peripheral white blood cell count greater than 10,000/mm^3 and an erythrocyte sedimentation rate greater than 15 mm/hr. In addition, endocervical gonorrhea and *Chlamydia* infection may be present simultaneously in 10 to 30 percent of cases. Ultrasonography of the pelvic cavity helps detect pelvic abscesses. A study involving the use of pelvic ultrasonography in adolescents with PID showed that the presence of fluid in the cul-de-sac was not helpful in differentiating patients with and without PID.[78] Almost 20 percent of patients with PID had a tubo-ovarian abscess; in the absence of a tubo-ovarian abscess, adnexal volume was significantly larger in adolescents with PID than in adolescents without it.[78] Ultrasonography (transvaginal) can be very useful in ruling out other diagnoses and defining adnexal masses.

The clinical diagnosis of PID is made by having a high index of suspicion of this entity. For practical reasons, the clinical criteria developed by Jacobsen and Westrom[111] and revised by the CDC[35] are recommended to aid in making the diagnosis and subsequently to increase the index of suspicion for PID (Table 42-5). When comparing the reliability of clinical criteria using endometrial sampling as the reference test,[35] the sensitivity of using one criterion—adnexal tenderness—was 95 percent, and the sensitivity of using three criteria—abdominal pain, cervical motion tenderness, and adnexal tenderness—was 83 percent.

TABLE 42-5 **Clinical Criteria for the Diagnosis of Acute Pelvic Inflammatory Disease**

Minimal Criteria
Lower abdominal or pelvic pain with one or more of the following: uterine or adnexal tenderness or cervical motion tenderness
Additional Criteria to Enhance Specificity
Temperature >38.3° C (>101.9° F)
Abnormal cervical or vaginal mucopurulent discharge
Presence of white blood cells on saline microscopy of vaginal secretions
Elevation of erythrocyte sedimentation rate
Elevated C-reactive protein
Laboratory documentation of cervical infection with *Neisseria gonorrhoeae* or *Chlamydia trachomatis* or both
Specific Criteria
Endometrial biopsy specimen with histopathologic evidence of endometritis
Transvaginal sonography or magnetic resonance imaging technique showing thickened fluid-filled or tubo-ovarian complex
Laparoscopic abnormalities consistent with pelvic inflammatory disease

From Centers for Disease Control and Prevention. Sexually transmitted disease treatment guidelines 2010. *MMWR Recomm Rep* 2010;59(RR-12):1–110.

The minimum criteria recommended for empirical treatment include abdominal pain with uterine tenderness or cervical motion tenderness or adnexal tenderness.[35] The more criteria that can be met, the more likely it is that a tubal infection is present. The differential diagnosis of PID is an acute abdomen. Conditions of the urinary tract that should be considered include cystitis, pyelonephritis, and urethritis. Gastrointestinal tract conditions include appendicitis, constipation, diverticulitis, gastroenteritis, inflammatory bowel disease, and irritable bowel syndrome. Gynecologic conditions include dysmenorrhea, ectopic pregnancy, endometriosis, endometritis, mittelschmerz, torsion or rupture of an ovarian cyst, ruptured follicle, septic abortion, threatened abortion, and pyogenic sacroiliitis. As in PID, establishing an early diagnosis of acute appendicitis and ectopic pregnancy is important.

Treatment

The major goals of treatment of PID are preservation of fertility and prevention of other long-term sequelae, including ectopic pregnancy. Although some data suggest

that women younger than 25 years old have a better fertility prognosis overall after having PID and ectopic pregnancy, no difference exists among age groups regarding tubal infertility specifically after PID.[155] Earlier initiation of treatment results in lower risk for developing infertility. Girls and women initially evaluated after more than 3 days of abdominal pain are found to have a 2.8-fold increased risk for having impaired fertility (tubal infertility or ectopic pregnancy) compared with those evaluated within 3 days of the onset of abdominal pain.[100] Generally, more severe PID has a higher risk for future infertility. In addition, more episodes of PID result in a higher risk for future infertility. After one episode, the risk for infertility ranges from 8 to 13 percent; after two episodes, the risk is 20 to 35 percent; and after three or more episodes, it is 40 to 75 percent.[190,206]

To reduce the incidence of sequelae associated with this condition, early recognition of PID, the use of broad-spectrum antibiotics to treat polymicrobial disease, careful clinical reevaluation 48 hours after initiating antibiotic treatment to assess antibiotic response, and evaluation and treatment of sexual partners are important. Screening the patient for other STIs, such as trichomoniasis, bacterial vaginosis, and syphilis, also is important.

Patients with PID often are treated on an ambulatory basis. The primary reason to hospitalize an adolescent with PID is to ensure compliance with medication when she is unable to follow or tolerate an outpatient oral regimen because of the seriousness of the sequelae and problems with compliance in this age group. Other reasons for hospitalization are an uncertain diagnosis, the presence of a tubo-ovarian abscess, pregnancy, infection with HIV, temperature greater than 38.5°C (101.3°F), nausea and vomiting precluding the use of oral medications, and lack of improvement after 48 hours of oral antibiotic treatment.

The recommendations of the CDC for treating PID in ambulatory and hospitalized patients address antibiotic coverage for the polymicrobial etiology of this condition (Tables 42-6 and 42-7).[35] In addition to antibiotic treatment, bed rest is recommended. Intravenous fluids are administered for hydration when necessary. When the diagnosis of PID is certain, oral analgesic agents may be prescribed. Close follow-up is recommended, with a bimanual examination performed after 48 hours of antibiotic treatment to assess the patient's response to treatment.[35] Overall, most studies show that response to antibiotic regimens is similar between HIV-positive and HIV-negative patients. The treatment recommendations for HIV-positive patients are no different.[34] Complications associated with PID are perihepatitis, tubo-ovarian abscess, hydrosalpinx (obstruction of the tube caused by scarring [Fig. 42-15]), chronic abdominal pain from adhesions surrounding the fallopian tubes and ovaries, recurrent PID, ectopic pregnancy, and infertility.[190,215]

Perihepatitis

The classic manifestation of perihepatitis, or Fitz-Hugh–Curtis syndrome,[155] is severe right upper abdominal pain that often radiates to the shoulder. Concurrent left upper abdominal pain also may be present. Lower abdominal pain and evidence of acute or subacute PID are frequent

FIGURE 42-15 ■ Large hydrosalpinx, the result of gonorrheal salpingitis in an older teenage girl who had repeated gonorrheal infections. The other tube also was diseased.

TABLE 42-6 Ambulatory Management of Pelvic Inflammatory Disease

Ceftriaxone 250 mg IM in a single dose *or* cefoxitin 2 g IM in a single dose *plus* probenecid 1 g orally in a single dose *or* other parenteral third-generation cephalosporins (e.g., ceftizoxime or cefotaxime)
Plus
Doxycycline 100 mg PO two times a day for 14 days
With or without
Metronidazole 500 mg PO twice a day for 14 days

From Centers for Disease Control and Prevention. Sexually transmitted disease treatment guidelines 2010. *MMWR Recomm Rep* 2010;59(RR-12):1–110.

TABLE 42-7 Inpatient Treatment of Pelvic Inflammatory Disease

Regimen A
Cefoxitin 2 g IV every 6 hr *or* cefotetan 2 g IV every 12 hr
Plus
Doxycycline 100 mg every 12 hr PO or IV
Regimen B
Clindamycin 900 mg IV every 8 hr
Plus
Gentamicin loading dose 2 mg/kg IV or IM, followed by a maintenance dose 1.5 mg/kg every 8 hr

From Centers for Disease Control and Prevention. Sexually transmitted disease treatment guidelines 2010. *MMWR Recomm Rep* 2010;59(RR-12):1–110.

Note: The above regimens are given for at least 24 hr after the patient improves. After discharge from the hospital, the patient is continued on doxycycline 100 mg PO two times per day for a total of 14 days.

findings. The right upper quadrant pain lasts about 48 hours. Nausea, fever, and leukocytosis are common manifestations. Elevation of the erythrocyte sedimentation rate and liver enzymes may be present. The pathogenesis of perihepatitis is thought to be from direct spread of *N. gonorrhoeae* and *C. trachomatis* from the fallopian tubes into the peritoneal cavity, along the paracolic sulci. From there, they reach the subphrenic space and hepatic surface. Spread from the reproductive tract also is possible via the retroperitoneal lymphatics.[155]

The diagnosis is made by having a high index of suspicion. Perihepatitis frequently mimics cholelithiasis, hepatitis, pleuritis, subphrenic abscess, perforated peptic ulcer, nephrolithiasis, appendicitis, ectopic pregnancy, abdominal trauma, and pancreatitis. Treatment of this condition is similar to treatment of PID.

Tubo-ovarian Abscess

The formation of a tubo-ovarian abscess is a late manifestation of PID. The incidence of tubo-ovarian abscess ranges from 14 to 38 percent in hospital-based adolescents and adults with salpingitis.[78,82,124,194] Tubo-ovarian abscesses rarely are seen in adolescents and young women who are not sexually active, and alternative diagnoses involving congenital anomalies must be considered.[53,188] Organisms isolated from tubo-ovarian abscesses in adolescents who do not report sexual activity include *E. coli*, α-hemolytic streptococci and *Pasteurella multocida*. The actual cause for ascending infection in these cases is unknown. Alterations in cervical secretions, which usually serve as a barrier, have been hypothesized. The abscess typically results from a mixture of facultative and anaerobic bacteria, with facultative bacteria dominating the early phase of infection, and bacterial metabolic products producing an environment of low oxygen tension that favors the growth of anaerobic bacteria.[155]

The most common organisms recovered from tubo-ovarian abscesses in sexually active women include: *E. coli*, *Bacteroides fragilis*, other *Bacteroides* spp., *Peptostreptococcus*, *Peptococcus*, and aerobic streptococci.[167] Diagnosing the presence of a tubo-ovarian abscess clinically usually is difficult. Adolescents with a tubo-ovarian abscess tend to seek care later in their menstrual cycle than do girls without a tubo-ovarian abscess.[194] Bimanual examination frequently does not reveal a pelvic mass.[42] Four potentially useful clinical features that suggest the presence of a pelvic abscess are pain, persistent fever, adnexal tenderness (for 7 days), and an erythrocyte sedimentation rate greater than 30 mm/hr.[42] Ultrasonography of the pelvis is valuable in confirming the presence of an abscess.[78]

The prompt administration of antibiotics has reduced greatly the incidence of pelvic abscess. Most of those encountered today are in adolescents who have not had adequate care and have delayed seeking treatment.[83,198]

A conservative approach is favored for the treatment of a tubo-ovarian or ovarian abscess (i.e., bed rest, supportive care, intravenous antibiotics, and nonsteroidal analgesics).[194] This approach is appropriate when the adolescent (including an immunocompromised adolescent) is hemodynamically stable and the abscess is 9 cm or less in diameter. An abscess larger than 10 cm has a 60 percent chance, a 7- to 9-cm abscess has a 35 percent chance, and a 4- to 6-cm abscess has a 20 percent chance of requiring surgical intervention.[167] Surgical intervention may be needed during the initial period if hemodynamic instability and sepsis with imminent rupture is suspected. The choice of antibiotics should be based on effectiveness against lactamase-producing anaerobes, adequate coverage against resistant *Bacteroides* spp., penetration into the abscess, and ability to remain stable in an abscess environment. The antibiotic regimens for inpatient treatment of PID fulfill these considerations and are appropriate for the treatment of tubo-ovarian abscess (see Table 42-7). As is the case with cefoxitin, cefotetan, and clindamycin, metronidazole provides good activity against anaerobes.[35] Many hospitals prefer the use of triple antibiotics cefoxitin and gentamicin plus clindamycin or metronidazole.

A clinical response to treatment consisting of a decrease in pain, fever, and total leukocyte count should be noted in 72 hours. Pelvic ultrasonography should be repeated at this time to note any further increase in the size of the abscess. The duration of intravenous and oral antibiotic therapy for a tubo-ovarian abscess should be at least 21 days. The patient may begin oral antibiotics when she is afebrile and asymptomatic and when the size of the abscess has stabilized. The abscess either resolves without drainage or becomes encapsulated. The latter eventually "points" either in the cul-de-sac or anteriorly in the abdominal wall.

The fertility rate after treatment of tubo-ovarian abscesses may be 20 to 50 percent with conservative medical and surgical approaches.

Oophoritis

Oophoritis is a rare condition today and refers to inflammation of the substance of the ovaries, the oocytes in particular. Viral exanthems such as mumps and cytomegalovirus can be complicated by oophoritis, especially in immunosuppressed children and adolescents. Improved immunization practices have decreased the prevalence of mumps and its complications, including oophoritis. However, an outbreak of mumps in children occurred in Centerville, Ohio, in 1981.[205] The severity of mumps (including oophoritis) was higher in children who had not been previously immunized in contrast to those who were immunized against mumps.[205] The presence of an enlarged, tender, boggy, smooth, mobile ovary in a child with mumps or one of the exanthems suggests oophoritis. Treatment is palliative, with analgesics given for discomfort and fever.

SECTION VI

GASTROINTESTINAL TRACT INFECTIONS

CHAPTER 43

Esophagitis

Paul Krogstad • Robert S. Venick

Infectious esophagitis is distinct from other gastrointestinal infections in that it is a rare finding in previously healthy individuals, is predominantly of fungal and viral etiology, and usually is an indicator of a primary or secondary immunodeficiency state. In nonimmunocompromised children, infectious esophagitis frequently is associated with conditions that compromise the esophageal defense mechanisms.[46]

In view of the numerous predisposing conditions, the incidence of infectious esophagitis in children is difficult to quantify. It has been reported frequently after patients have undergone chemotherapy or radiation therapy for hematologic malignancies and after solid organ and hematopoietic stem cell transplantation. Infectious esophagitis has been reported in 3 percent of patients with ataxia-telangiectasia.[29] Before the availability of highly active antiretroviral therapy (HAART), 8 to 10 percent of children infected with human immunodeficiency virus (HIV) developed *Candida* esophagitis.[4,7,37] Despite the availability of HAART, *Candida* esophagitis remains one of the most common opportunistic infections in HIV-infected children and generally is associated with low $CD4^+$ T-cell count (<100/μL), prior episodes of oropharyngeal candidiasis, high plasma HIV-1 load, and neutropenia (<500/μL).[7,8,45]

PATHOPHYSIOLOGY AND CAUSATIVE ORGANISMS

The defense mechanisms of the esophagus against infection include motility (continuous flow of luminal contents, which discourages colonization by microbes), a mucosal lining of stratified squamous epithelium that is resistant to microbial invasion, and local and systemic immune responses. Disruption of any of these protective factors may lead to esophageal infections. Immunosuppression (as seen in patients with the acquired immunodeficiency syndrome [AIDS] or after organ transplantation), chronic mucocutaneous candidiasis, malignancy, chemotherapy, and prolonged corticosteroid treatment are the most common predisposing factors for fungal and viral infection of the esophagus.[6-8,19,27,37] In immunocompetent children, dysmotility of the esophagus, in addition to mucosal injury secondary to gastroesophageal reflux, can render the esophagus vulnerable to infections.

Most esophageal infections are caused by fungi and viruses.[3] *Candida* spp. (especially *Candida albicans*), herpes simplex virus (HSV), and cytomegalovirus (CMV) are the major pathogens. The esophagus can be infected by local invasion (*Candida*, HSV, bacteria), as a result of systemic infection (CMV, *Candida*, *Pneumocystis*), or by contiguous spread from the mediastinum or neck (tuberculosis, retropharyngeal abscess).[4,37,46] Infections with fungi such as *Pneumocystis*, *Aspergillus*, and *Histoplasma* spp.; viruses such as varicella-zoster virus (VZV), human papillomaviruses, Epstein-Barr virus, and HIV; and protozoa such as *Cryptosporidium* and *Leishmania donovani* are less frequent, yet well-documented causes of esophagitis.*

Bacterial infections of the esophagus probably are underreported. Ten to 16 percent of esophageal infections can have a bacterial etiology, mostly in granulocytopenic patients and as secondary infection in fungal or viral esophagitis. Gram-positive and gram-negative oropharyngeal bacterial flora and *Mycobacterium tuberculosis* are the common pathogens causing esophagitis.[13,44] *Helicobacter pylori* has been isolated from involved tissue in Barrett esophagitis. This "infection" seems, however, to be related more to gastroesophageal reflux disease rather than to direct invasion of the esophagus by *H. pylori*.[31]

CLINICAL FEATURES

Patients with infectious esophagitis can present with esophageal, abdominal, or systemic symptoms (Table 43-1). Oropharyngeal lesions suggestive of HSV or *Candida* may serve as a clue that esophageal involvement is also present. Odynophagia and dysphagia are the most common symptoms of esophagitis, but they may not be apparent in small children.[7,8,35] In adults, 59 to 79 percent of patients with documented esophageal infection had these symptoms.[3] Children also may describe a sensation of food "sticking" behind the sternum or a feeling of a food or liquid bolus passing through the chest.

Nearly all patients with AIDS and oral candidiasis and odynophagia have endoscopic evidence of esophageal candidiasis.[5,7,39] Some patients ultimately proven to have esophagitis have no signs or symptoms at presentation, however. Children who develop esophageal candidiasis despite being treated with HAART are less likely to have typical symptoms (e.g., odynophagia and retrosternal pain) or to have concomitant oropharyngeal candidiasis.[8] Similarly, approximately one fourth of adult patients with esophageal candidiasis are asymptomatic.[3]

Drooling is an unusual manifestation in esophagitis per se but may be present with pharyngeal involvement.

*References 9, 14, 15, 17, 18, 23, 30, 34, 41.

TABLE 43-1 **Signs and Symptoms of Infectious Esophagitis**

Dysphagia
Odynophagia
Oral lesions
Nausea/vomiting
Abdominal pain
Fever
Diarrhea
Cough
Rash
Hematemesis

Fever is caused mostly by systemic or secondary infection, such as disseminated CMV disease or tuberculosis, or complications that occur after esophageal perforation. Fever does not occur commonly in bacterial esophagitis. Cough is characteristic of tuberculosis, tracheobronchial fistulas, or high-grade esophageal obstruction.

Nausea and vomiting are associated more commonly with CMV esophagitis. The abdominal pain in esophagitis may be caused by referred pain from inflammation of the distal one third of the esophagus, associated gastritis (as in CMV infection), or concomitant intra-abdominal infections in immunocompromised hosts. A maculopapular truncal rash and fever may be present in patients with idiopathic esophageal ulceration during acute HIV seroconversion.[34] Diarrhea can be present in CMV infection (diffuse involvement of the gastrointestinal tract) or HIV infection (opportunistic enteral infections, HIV enteropathy). In one report of fungal esophagitis in children, hematemesis was the most common initial symptom.[46] Finally, because physicians seldom seek evidence of esophagitis in the absence of dysphagia or odynophagia, infectious esophagitis may be underdiagnosed in infants and children.

Oral lesions are seen in patients with *Candida*, HSV, or HIV esophagitis, but they rarely are present with CMV infection and tuberculosis. Oral thrush is a common occurrence, however, in infants and immunocompromised patients. The frequency of *Candida* esophagitis in infants with oral thrush is unknown. The presence of oral thrush and esophageal symptoms does not exclude concomitant esophageal infection with pathogens other than *Candida* or the esophageal ulcerations associated with acute HIV infection. Oropharyngeal lesions are less common findings in HSV esophagitis than in *Candida* esophagitis. Recurrent cold sores, vesicular lesions on the nasolabial folds, and esophageal symptoms sometimes are seen as initial features of HSV esophagitis in immunocompetent adults and children, but their absence does not exclude HSV infection.[3,35]

DIFFERENTIAL DIAGNOSIS

Esophagitis can be caused by the following mechanisms: gastroesophageal reflux, chemical irritation (including medications or caustic ingestions), immunologic factors (i.e., cow's milk protein allergy), traumatic factors (nasogastric tube), radiation therapy, cancer chemotherapy, systemic disease (e.g., Crohn disease or chronic granulomatous disease), eosinophilic esophagitis, or motility disorders.

"Pill" esophagitis may be identified by history. Pathologic gastroesophageal reflux is the most common cause of esophagitis in children. In previously healthy children, esophageal symptoms are likely to be caused by reflux esophagitis, whereas in immunocompromised patients the physician needs to rule out infectious esophagitis. Secondary bacterial or fungal infections can be present in reflux esophagitis and Chagas disease, especially with severe inflammation and obstruction. Absence of reflux symptoms (long-standing heartburn, a water brash taste in the mouth, vomiting, spitting up [in infants], pillow wetting, or coughing) tends to exclude reflux esophagitis. Achalasia, diffuse esophageal spasm, foreign body impaction, and mediastinal or retropharyngeal abscesses can cause esophageal symptoms and may result in secondary infection. Besides imaging and endoscopy (see later), other available tools include 24-hour intraesophageal pH probe, esophageal impedance, and manometry.

DIAGNOSIS

Establishing a specific diagnosis is essential for management of infectious esophagitis, particularly because fungal and bacterial superinfections occur commonly in the setting of viral esophagitis. Although the clinical profile, barium esophagogram, and endoscopic appearance can provide some clue as to the etiology of esophagitis, histopathology, immunohistochemistry, and culture of endoscopic and brush biopsy specimens are essential for confirmation of specific pathogens. Serology for HSV, CMV, or Epstein-Barr virus may help establish the diagnosis in some cases by providing evidence of acute infection. DNA detection methods also may provide evidence of viremia with these herpesviruses. Detection of fungal or viral esophagitis in an ostensibly healthy host should prompt an evaluation for the presence of primary or secondary immunodeficiency states, including HIV infection.

Barium Esophagography

The usefulness of an esophagogram in diagnosing infectious esophagitis is limited because it does not separate specific causes; normal or nonspecific findings also can be found in some cases of esophagitis. These studies are useful for assessing dysmotility, which can be a predisposing factor for esophagitis, and for excluding obstruction, perforation, and fistulas of the esophagus. Barium studies are not indicated if endoscopy is planned. Double-contrast barium esophagography with air and barium, which details the mucosal lining, is the radiologic investigation of choice, but many children may not tolerate this procedure.[25]

Candida esophagitis generally is diffuse, whereas HSV or CMV lesions are found more frequently in the mid to distal portion of the esophagus. Discrete longitudinal

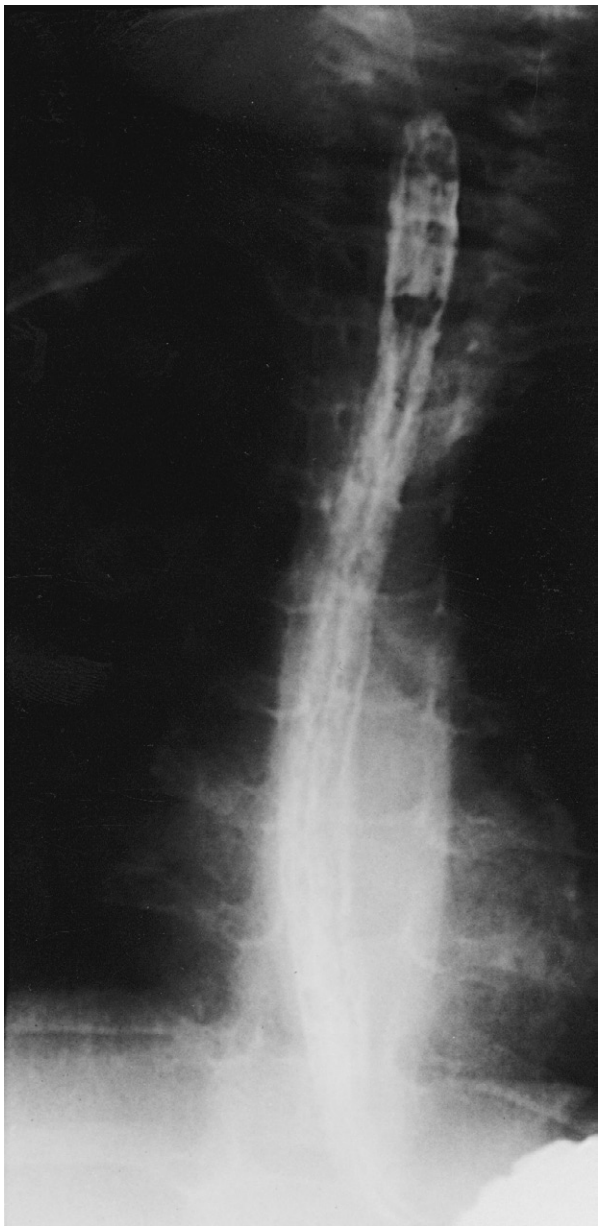

FIGURE 43-1 ■ *Candida* esophagitis. Barium esophagogram shows diffuse mucosal irregularity suggestive of inflammation and longitudinal filling defects suggestive of plaques. (Courtesy Sjirk Westra, MD, Division of Pediatric Radiology, David Geffen School of Medicine at UCLA, Los Angeles.)

plaques, a grossly irregular or "shaggy" appearance, or tiny nodular lesions with a granular radiographic appearance are characteristic of *Candida* esophagitis (Fig. 43-1). The presence of discrete superficial stellate ulcers in the mid esophagus with normal-appearing surrounding mucosa is characteristic of HSV esophagitis, whereas CMV lesions may mimic HSV lesions on barium esophagography. Oval or elongated large ulcers are found mostly in CMV infection. Idiopathic esophageal ulceration is found in HIV infection.[24,43] Esophagograms of patients with tuberculosis can show intramural pseudodiverticula, extrinsic compression, or esophageal displacement by mediastinal lymph nodes and sinus tracts.[10]

FIGURE 43-2 ■ Endoscopic image of *Candida* esophagitis. Examination of the distal one third of the esophagus reveals whitish plaques with superficial ulceration of the esophageal mucosa. (See companion website on Expert Consult for a color version of this figure.)

Esophagoscopy

The diagnosis of esophagitis can be made on upper endoscopy with biopsies, although esophageal brushings often are of greater diagnostic yield. The technique for performing endoscopy with video-endoscopes miniaturized to a diameter of 4.8 mm has made the procedure far more tolerable in immunocompromised patients, infants, and small children. Such instruments allow for procedures to be performed with greater technical care, and these instruments have biopsy capabilities.

Characteristic macroscopic lesions are associated with some infectious agents, but the features of these lesions overlap considerably, and histopathologic or immunohistochemical analysis (or both) of endoscopic and brush biopsy specimens is essential for specific diagnosis. A diffuse esophageal lesion is characteristic of *Candida* infection, whereas CMV and HSV infections mainly involve the distal part of the esophagus. White, longitudinal plaques adhering to the mucosa are characteristic of *Candida* infection (Fig. 43-2).[20] Plaques from oral thrush, common findings in infants and immunocompromised children, can be washed away and reveal a nonulcerated underlying mucosa. Similar-appearing plaques also may be seen in CMV, HSV, bacterial, and "pill" esophagitis and after sucralfate ingestion.

Small, 1- to 3-mm vesicles are characteristic of HSV esophagitis, but by the time endoscopy is done these vesicles usually slough off and reveal sharply demarcated ulcers with a raised edge, necrotic base, and normal-appearing surrounding mucosa.[35] In progressive disease, these ulcers may coalesce to resemble *Candida* esophagitis.[1] Multiple superficial ulcers in the distal portion of the esophagus often are seen in CMV esophagitis. Large elongated ulcers also are typical manifestations of CMV infection, but they may occur in idiopathic esophageal ulcerations in HIV infection as well.[24] Complete

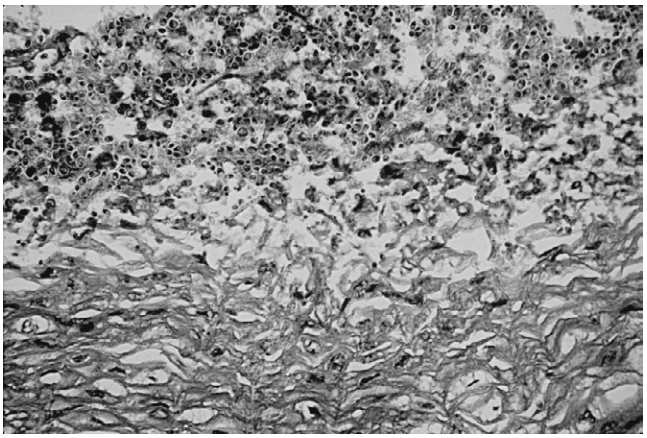

FIGURE 43-3 ■ *Candida* esophagitis. Photomicrograph shows yeastlike organisms in the esophageal mucosa. (Methenamine silver.) (Courtesy Klaus Lewin, MD, Division of Pediatric Radiology, David Geffen school of Medicine at UCLA, Los Angeles.)

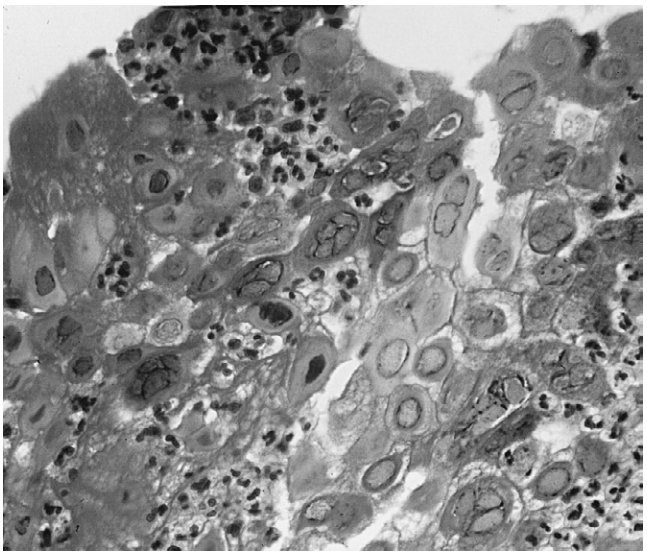

FIGURE 43-4 ■ Herpes simplex virus esophagitis. Photomicrograph shows viral inclusions in squamous epithelium. (Hematoxylin-eosin.) (Courtesy Klaus Lewin, MD, Department of Pathology, UCLA Medical Center, Los Angeles.)

denudation of the mucosa is an unusual finding with CMV infection.[40] Endoscopy done in patients with VZV esophagitis can show vesicles, discrete ulcers, or necrotizing esophagitis, depending on the stage of the disease. Tubercular ulcers of the esophagus usually are of varying size, distinct, and shallow with a necrotic base.

Endoscopic biopsy specimens should be obtained from the edge and the base of the lesions. The pathologist should be alerted to the possibility of fungal, viral, and polymicrobial infection. Appropriate fixatives should be used for routine hematoxylin and eosin stain, Gram stain, and special stains for fungi and bacteria such as *Mycobacterium*. *Candida* and *Aspergillus* can be shown by silver stain, periodic acid–Schiff stain, or Gram stain (Fig. 43-3). Diagnostic histopathologic changes, such as multinucleated giant cells, ballooning degeneration, intranuclear Cowdry type A inclusion bodies, and margination of chromatin in HSV infection (Fig. 43-4) and

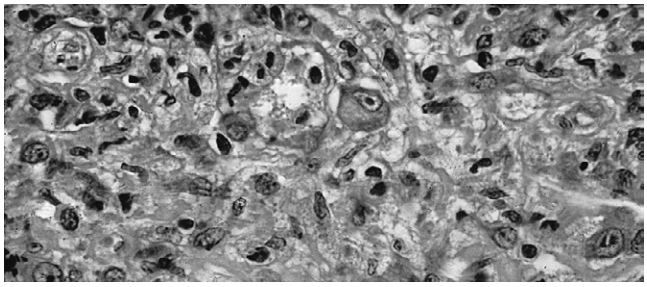

FIGURE 43-5 ■ Cytomegalovirus esophagitis. Photomicrograph shows intracytoplasmic inclusion bodies in the lamina propria. (Hematoxylin-eosin.) (Courtesy Klaus Lewin, MD, Department of Pathology, David Geffen School of Medicine at UCLA, Los Angeles.)

amphophilic intranuclear inclusions and small multiple cytoplasmic inclusion bodies in CMV infection (Fig. 43-5), can be diagnostic. Immunohistochemical studies and DNA hybridization techniques often are required to establish the diagnosis, however.

Viral culture, with or without immunohistochemical techniques, may aid in confirmation. Material obtained by endoscopy-guided brush biopsy can reveal the features of *Candida* or viral infection described earlier. If abdominal pain, fever, or other unusual symptoms are present, the possibility of disseminated or abdominal infection should be excluded by appropriate investigations.

TREATMENT

Candida Esophagitis

Treatment of esophageal candidiasis requires systemic antifungal therapy. Topical therapy may produce an initial response, but early treatment failures are common.[33] Systemic therapy with newer triazole medications (fluconazole, itraconazole solution, or voriconazole) is now the preferred approach.[32] Numerous trials have been done comparing the azole agents, most often in adults with AIDS. Patients are less likely to respond and more likely to experience drug-related toxicity when treated with ketoconazole compared with fluconazole.[11] Oral fluconazole and itraconazole suspension seem comparable in efficacy for initial therapy, and some patients whose disease fails to respond to fluconazole may see improvement with subsequent itraconazole therapy.[12,36,44] Regardless of the initial severity of esophagitis, voriconazole and fluconazole seemed comparable in efficacy in one study, although toxicity occurred more commonly with voriconazole.[2,8] However, the pharmacologic interactions between triazole antifungal medications with immunosuppressive medications and other drugs may be problematic in some patients.

Overall, experience with the triazole medications supports recommendations for the initial use of oral fluconazole therapy for *Candida* esophagitis. Therapy generally is given for 14 to 21 days. Intravenous administration of azole medications may be used for patients with severe dysphagia.[26,32]

Infection with azole-resistant variants of *Candida*, including species with intrinsic or acquired resistance to

fluconazole (e.g., *Candida krusei*), may occur.[2,8] Although pediatric data currently are limited, large-scale studies in adults have shown that intravenous therapy with echinocandin agents (caspofungin, anidulafungin, or micafungin) is an alternative to azole therapy.[26,32,42]

Intravenous amphotericin B deoxycholate remains an alternative for patients with disease that is refractory to treatment with azole medications.[21,32] Nephrotoxicity is a major toxic effect of amphotericin B, but brief, low-dose therapy (7 to 14 days, 0.3 to 0.7 mg/kg/day) generally is sufficient to treat esophagitis. Lipid formulations of amphotericin B also may be useful for treating refractory disease, but they are more expensive and not known to be superior in efficacy or lower in toxicity for the treatment of *Candida* esophagitis than low doses of deoxycholate formulation.

OTHER CAUSES OF FUNGAL ESOPHAGITIS

Cases of esophagitis caused by *Aspergillus*, *Mucor*, *Cryptococcus*, and *Histoplasma* spp. have been described. Optimal therapy has not been established, but systemic therapy, as for other manifestations of invasive infection with these organisms, has been successful. Currently, this approach would involve the use of intravenous or oral triazole agents or an amphotericin B preparation. Echinocandins (micafungin, caspofungin, or anidulafungin) may be useful for *Aspergillus* or *Histoplasma* infections, but they have no activity against cryptococci.

VIRAL ESOPHAGITIS

Although spontaneous resolution of HSV esophagitis may occur in some individuals, antiviral therapy for HSV esophagitis generally is advised. Immunocompromised patients usually are treated with intravenous acyclovir, but in older patients valacyclovir and famciclovir may be useful alternatives because of their clinical efficacy and convenient dosing schedule.[28] Ganciclovir is used for CMV infection.[3,38] Acyclovir is the treatment of choice for VZV infection, and the prophylactic use of acyclovir has reduced effectively the rate of VZV infection after transplant surgery. Foscarnet is an alternative treatment for patients with HSV, VZV, or CMV who cannot tolerate or do not respond to initial therapy with acyclovir or ganciclovir. Therapy for 14 to 21 days usually is recommended for esophagitis caused by these herpesviruses. HIV-associated idiopathic ulcers do not respond to empirical antiviral or antifungal therapy, but they may respond to treatment with thalidomide.[16]

BACTERIAL ESOPHAGITIS

Bacterial esophagitis typically occurs in immunocompromised hosts and may involve gram-positive or gram-negative bacteria, or a mixture of both. In immunocompromised hosts, esophagitis may be associated with bacteremia. Consequently, empirical therapy should include broad-spectrum antibacterial agents active against *Staphylococcus aureus*, viridans streptococci, and aerobic gram-negative organisms. Blood cultures always should be performed to exclude bacteremia.[44]

Esophageal infections with *M. tuberculosis* or atypical mycobacteria are treated with regimens appropriate for other systemic infections with these organisms. Lack of response to appropriate therapy may indicate concomitant superinfection by other organisms or resistance to the drugs used. Repeat endoscopy is indicated for documenting eradication of infection.

PROGNOSIS

Candida esophagitis carries a poor prognosis for patients with AIDS. Survival is approximately 1 year after an episode of *Candida* esophagitis in children with untreated HIV infection, and *Candida* esophagitis is an indication for administration of antiretroviral therapy.[4,34] Fungal esophagitis, if not treated successfully, can lead to esophageal strictures, obstruction, perforation, and fistulas.[22,27] Viral esophagitis usually does not have any significant long-term sequelae.

CHAPTER 44

Approach to Patients with Gastrointestinal Tract Infections and Food Poisoning

Theresa J. Ochoa • Mara Zambruni • Elsa Chea-Woo

Gastrointestinal infections can be caused by a wide array of pathogens, including bacteria, viruses, and parasites. Chemical food poisoning further broadens the spectrum of diseases. The cardinal symptoms of enteric infections/intoxications are diarrhea, emesis, and abdominal cramps in various combinations, but some enteropathogens cause less specific systemic syndromes and neurologic disorders that are the hallmark of a few food intoxications. A high degree of suspicion is necessary in these cases to formulate the correct diagnosis.

Irrespective of the underlying cause, the approach to a patient with suspected gastrointestinal infection or food poisoning starts with the assessment of patient dehydration status and need for immediate clinical intervention: the timely correction of fluid loss is the single most important intervention to decrease mortality. The next step consists of a thorough interview and physical examination aimed at formulating a presumptive differential diagnosis: circumstances of disease onset, constellation of symptoms and signs, characteristics of stools, geographic location and season of the year, and presence of other sick contacts normally are sufficient to orient the physician toward the correct cause of infection. A careful choice of diagnostic tests will not only confirm the diagnosis and establish a plan of treatment but also provide grounds for infection control actions and prevention of outbreaks.

In this chapter we review the essential information regarding epidemiology and epidemiologic classifications of enteric diseases, characteristics of common pathogens, general management of patients with diarrhea, laboratory diagnosis, and updated recommendations for treatment and prevention.

EPIDEMIOLOGY

Gastrointestinal infections represent a major cause of morbidity and mortality among children. Worldwide it is estimated that 1.6 billion episodes occur per year among children younger than 5 years of age, leading to 1.3 million deaths per year.[49,192,291] The World Health Organization (WHO) and United Nations International Children's Emergency Fund (UNICEF) Child Health Epidemiology Reference Group (CHERG) have published estimates of the distribution of child deaths by cause in 2010, with time trends since 2000.[291]

Worldwide rates for diarrhea-associated deaths in children younger than 5 years of age in 2010 were estimated to be 0.7 million, a figure consistently lower than the 1.8 million estimated in 2003. Significant differences, however, exist among geographic areas related to age, race, household income, access to health care, and sanitation level. Diarrheal diseases accounted for 4 percent of deaths among children younger than age 5 in the Americas, Europe, and western Pacific regions, whereas in Africa, South East Asia, and eastern Mediterranean areas they caused up to 12 percent of deaths.[291] In the United States, diarrhea-associated morbidity and mortality among children younger than 5 years of age significantly decreased over the past century owing to improved living standards, sanitation systems, access to clinical care, and clinical management. In 2005 to 2006 the estimated rates of diarrhea-associated deaths in this country were 2.3 per 100,000 children per year: case-fatality ratios were higher among young infants, males (M:F ratio 1.3), black children (relative risk 3.9 compared with white children), and children from southern counties.[147] Racial and geographic differences likely reflect disparities in socioeconomic status and access to quality health care. Since rotavirus vaccination was included in the U.S. vaccination program in 2006, a substantial reduction in gastroenteritis among young children has been observed: from 2008 to 2009 reported rates of all-cause gastroenteritis hospitalizations and rotavirus-associated hospitalizations were reduced, respectively, 31 to 33 percent and 61 to 72 percent compared with the prevaccination era.[125] Similar declines in all-cause gastroenteritis and rotavirus-enteric infections rates were observed in other high and middle income countries where vaccination programs were implemented. It is hoped that vaccine use in low-income countries, as endorsed by the WHO, will have a substantial impact on diarrheal overall burden of disease.[457]

There is also growing awareness of potential long-term disability caused by repeated episodes of diarrheal disease, especially in children living in developing countries: malnutrition, failure to thrive, and impaired cognition have all been described as consequences of protracted diarrhea.[191,278,369]

Gastrointestinal infections are fundamentally acquired in two ways: by fecal-oral transmission and by contaminated food or water ingestion. The relative importance of the two routes, the risk for a child to be infected, and

the type of microbes involved vary with age, immune status, and type of environmental exposures. Most cases of sporadic diarrhea occur in children younger than 5 years old, although all age groups can be affected. Breast-fed infants are less likely to acquire gastrointestinal infections because of the lower exposure to contaminated food and water and the protection granted by human milk components such as secretory antibodies, glycans, lactoferrin, leukocytes, cytokines, and other components produced by the mother's immune system. During and after weaning the risk of diarrhea increases.

Epidemiologic Categories of Diarrhea

Information regarding host immune status and environmental exposures normally allows for classification of disease into broad epidemiologic categories helpful to narrow the differential diagnosis: (1) diarrhea acquired in institutional settings, (2) antimicrobial-associated diarrhea, (3) diarrhea in immunosuppressed hosts, (4) traveler's diarrhea, and (5) foodborne or waterborne diarrhea (food poisoning).

Diarrhea Acquired in Institutional Centers: Childcare Centers

Gastrointestinal infections acquired in institutional settings are normally caused by highly contagious pathogens transmitted either by person-to-person contact, fomites, or ingestion of contaminated food. A typical setting for the pediatric population is daycare centers. Rotavirus, *Shigella* spp., and *Giardia* are the most common pathogens reported, but, as laboratory diagnosis improved, a number of other pathogens have been implicated, including *Cryptosporidium*, astrovirus, enteric adenovirus, calicivirus, hepatitis A, sapovirus, *Escherichia coli* O157:H7, and *Salmonella*.[114,284,471] Rigorous hygiene practices, exclusion or cohorting of sick children from daycare, and judicious use of antimicrobial agents are all effective strategies for infection control.[272] Criteria for child exclusion from daycare attendance and duration of exclusion have been published.[56,284]

Antimicrobial-Associated Diarrhea

Intestinal microbiota play a major role in gastrointestinal function and immune system homeostasis. Antimicrobial agents induce significant modification of enteric flora both in terms of diversity and bacterial biomass.[492] Such modification, which can persist long after the inciting agent has been discontinued, can result in altered gastrointestinal function and increased susceptibility to opportunistic pathogens such as *Clostridium difficile* or *Candida albicans*.[492] Diarrhea is a common side effect of antibiotics, occurring in 11 to 40 percent of the children treated with antimicrobial agents.[245] The spectrum of disease ranges from a mild self-resolving illness to pseudomembranous colitis, toxic megacolon, and possibly death.[38,51] Type and dose of antibiotic and host characteristics affect the severity of clinical manifestations. The epidemiology of *C. difficile* among children is not well understood.

C. difficile is the most common bacterial agent associated with severe antimicrobial-associated diarrhea. Enterotoxin A and cytotoxin B account for most of its virulence. Since the early 2000s, rates and severity of *C. difficile* infections have been increasing among adults and to a less extent in children, in part owing to the emergence of a hypervirulent strain called BI/NAP1/027.[304] This strain produces higher amounts of toxins A and B, and a third toxin called binary toxin is frequently resistant to fluoroquinolones and is associated with more severe disease.

Prior use of antibiotics is the single most important risk factor for *C. difficile* disease. Nearly all the antibiotics have been implicated, but penicillins, cephalosporins, clindamycin, and fluoroquinolones are the most frequently involved.[259] Additional risk factors for *C. difficile* infection in children include gastrostomy or jejunostomy tubes, use of proton pump inhibitors, altered intestinal mobility, and prolonged hospitalization.[408] Certain underlying diseases, such as immunodeficiency, malignancy, cystic fibrosis, and inflammatory bowel disease also predispose to *C. difficile* infection.[260]

Guidelines for diagnosis and treatment of *C. difficile* infection have been published by the Infectious Diseases Society of America (IDSA) and Society for Health Care Epidemiology of America (SHEA).*

Diarrhea in Immunosuppressed Host

Enteric infections are often a major problem in people with primary and secondary immunologic disorders.[24,405,506] The spectrum of disease and the type of involved pathogens can vary with the type of underlying deficit and the degree of immunosuppression. Patients with defects in cellular immunity (e.g., solid-organ or bone-marrow recipients, patients on chemotherapy for malignancies, children infected by human immunodeficiency virus [HIV] or born with congenital disorders) are mainly susceptible to pathogens with partial or predominant intracellular localization. Among common enteric pathogens, *Salmonella* and *Listeria* infections can result in disseminated, life-threatening diseases.[186,225] Viral infections by routine enteric pathogens such as rotavirus or norovirus can become chronic and debilitating.[155,265,363,502] Opportunistic agents such as cytomegalovirus can cause severe colitis in patients with advanced immune suppression, whereas Cryptosporidiosis and Microsporidiosis have been associated with persistent diarrhea.[314]

HIV-infected children represent a major group of immunosuppressed hosts, especially in some developing countries. Gastrointestinal dysfunction is common in these patients and can be related to a number of causes: concomitant infections, HIV enteropathy, malignancy, or highly active antiretroviral therapy (HAART) medicines. Besides the conventional enteric pathogens, opportunistic agents can cause significant disease in patients with advanced disease. In addition to protozoal infections like Microsporidiosis and Cryptosporidiosis, *Mycobacterium avium* complex is a common cause of persistent diarrhea and mainly affects the small intestine.[314] Cytomegalovirus

*Diseases of the gastrointestinal tract that fulfill the Centers for Disease Control and Prevention surveillance case definition of AIDS.

can cause diffuse and severe ileocolitis and dysentery-like illness. *C. difficile* can play a role, especially in children previously treated with antibiotics. *Salmonella* infection is associated with a high risk of septicemia and should be treated aggressively.[148] A description of enteropathogens causing infections in HIV-infected patients is provided in Table 44-1.

The advent of antiretroviral treatment has dramatically changed the epidemiology of opportunistic infections in HIV-infected children.[331,385] A study in adults examined the annual incidence of bacterial diarrhea before and during the HAART era in a large cohort of people with HIV infection.[331] Between 1992 and 2002, the overall rate of bacterial diarrhea in people with clinical acquired immunodeficiency syndrome (AIDS) decreased (odds ratio, 0.4; 95% confidence interval, 0.2 to 0.6). HAART can result in complete clinical, microbiologic, and histologic responses in patients with AIDS infected with *Cryptosporidium parvum* and *Enterocytozoon bieneusi*[69] and in patients with HIV enteropathy.[273] Guidelines for prevention of opportunistic infections, including those involving the gastrointestinal tract, can be found on the internet.*

*www.aidsinfo.nih.gov/

Severe defects in humoral immunity, such as X-linked agammaglobulinemia or common variable immunodeficiency, are often associated with persistent diarrhea and malabsorption syndrome; rotavirus and *Giardia lamblia* can be etiologic factors.[363] Enteric infections caused by *Campylobacter jejuni* and *Salmonella* spp. are more frequent and can be more severe and prolonged than in immunocompetent individuals.

Traveler's Diarrhea

Traveler's diarrhea is the most common illness reported by individuals traveling from high-income countries to middle and low income areas: occurrence as high as 40 to 60 percent is reported.* The most important determinant of risk is travel destination. World regions are divided into three risk categories: low-risk areas include United States, Canada, Western and Northern Europe, Australia, New Zealand, and Japan; intermediate-risk areas include Eastern Europe, South Africa, and some Caribbean Islands; and high-risk areas include most of Asia, Africa, Middle East, and Central and South America.[105,358]

Half of travelers experience diarrhea within the first few weeks after arrival. A variety of intestinal pathogens can be responsible for traveler's diarrhea.[48,216,348,358,422] Bacteria account for 80 to 90 percent of the cases: enterotoxigenic *E. coli* (ETEC) is the most common pathogen, followed by *Campylobacter jejuni*, *Shigella* spp., *Salmonella* spp., enteroaggregative *E. coli*, *Aeromonas* spp., *Plesiomonas* spp., and *Vibrio* spp. Parasites account for 10% of the cases: *Giardia lamblia* and *Cryptosporidium* are the most common pathogens; *Cyclospora*, *Entamoeba*, and *Dientamoeba* are occasionally encountered. Viruses represent 5 to 8 percent of cases: rotavirus, norovirus, and calicivirus are the most frequently reported.[105] However, based on the GeoSentinel Surveillance Network, the main pathogens isolated from international travelers with gastroenteritis are parasites (65%), followed by bacteria (31%) and viruses (3%).[449]

Clinical illness varies, reflecting the diversity of causative agents. Typically, illness presents as loose stools over a 24-hour period, accompanied by fever, nausea, vomiting, and abdominal cramping. Tenesmus and bloody diarrhea are less common. An incubation period of 6 to 48 hours normally suggests a bacterial or viral etiology, whereas parasites tend to have longer incubation periods and rarely present in the first week after travel; an exception is *Cyclospora cayetanensis*, which can present as an acute illness resembling bacterial pathogens. Traveler's diarrhea is normally a mild, self-limited illness that can resolve spontaneously in 3 to 5 weeks; protozoal diarrhea, however, can persist for months if untreated.

Children who travel are at risk of developing the same, well-known illnesses that affect adult travelers.[200] The etiology, treatment, and actual risk of these illnesses are not as well defined as in adults.[296] Treatment of traveler's diarrhea in children consists of fluid replacement and antibiotics. Antidiarrheal agents are not recommended for young children, although they can be considered for

*References 105, 134, 181, 216, 217, 358.

older children and adults, provided there is no gross blood in the stool or fever higher than 38.5 °C (101.3 °F).[17,105,143,217,296] Because access to good quality health care can be problematic in certain regions, travelers should be advised to take with them medications with expected activity against the prevalent bacteria. Antibiotic therapy has been shown to reduce duration of disease from several days to approximately 1 day. Recommended antibiotics for empirical treatment of traveler's diarrhea in adults and children are fluoroquinolones or azithromycin. Rifamixin is an alternative for afebrile nondysenteric diarrhea.[1,3,135,136,143]

Traveler's diarrhea is mainly a foodborne or waterborne disease: poor hygiene practices of food handlers, inadequate food storage and refrigeration, and high levels of environment contamination by fecal flora due to poor sanitation infrastructure are risk factors for acquiring enteric infections in developing countries. Travelers should be advised on safe practices regarding food and beverage consumption. No effective vaccinations are currently available for traveler's diarrhea. Similarly, chemoprophylaxis with antibiotics is not recommended in healthy travelers. Prophylactic treatment can be taken into consideration for hosts at increased risk of acquiring severe diarrhea, including patients with immunodeficiencies, malignancies, or chronic intestinal illnesses.[217]

Foodborne and Waterborne Diseases: Food Poisoning

Foodborne or waterborne diseases can result from ingestion of food or water contaminated with bacteria, viruses, parasites, or other types of chemical poisoning.[19,75] They can present either as sporadic cases or as outbreaks; the latter are defined as clusters of two or more individuals experiencing a similar illness after ingesting common food or water.[142,288,294] Foodborne and waterborne diseases represent major public health concerns and are subject to different degrees of surveillance across countries. In the United States, several surveillance systems coordinated by the Centers for Disease Control and Prevention (CDC) are in place to monitor foodborne and waterborne disease occurrence, track sources of contaminated food, identify emerging pathogens, and provide administrative guidance.

The Foodborne Disease Active Surveillance Network (FoodNet) was established by the CDC in 1996 to conduct population-based, active surveillance investigation of foodborne disease in the United States.[416] The surveillance includes laboratory-confirmed infections for nine common pathogens (*Campylobacter* spp., *Listeria* spp., *Salmonella* spp., *Shigella* spp., Shiga toxin–producing *E. coli* (STEC), *Vibrio* spp., *Yersinia* spp., *Cryptosporidium* spp., and *Cyclospora* spp.). Although some other important pathogens known to be transmitted by food are not actively tracked by the system, the control measures triggered by FoodNet inputs will likely have an impact on all foodborne infection. The National Notifiable Disease Surveillance System (NNDSS) is a passive surveillance database. Reportable foodborne diseases include botulism, listeriosis, salmonellosis, STEC infections, hemolytic-uremic syndrome, and vibriosis. A complete list of other CDC surveillance systems is available at the CDC website.*

The 2010 preliminary data from FoodNet surveillance showed that although foodborne infections caused by *Campylobacter* spp., *Listeria* spp., STEC O157, and *Yersinia* spp. decreased by an overall 23 percent compared with the period 1996 to 1998, rates for *Salmonella* spp. infections did not change significantly over the same period of time and incidence for *Vibrio* spp. infections actually increased. Population at extremes of age were the most affected, with highest incidence for *Salmonella*, *Campylobacter*, *Shigella*, STEC O157 and non-O157, *Yersinia*, and *Cryptosporidium* being reported among children younger than 5 years of age, whereas individuals older than 60 years of age had the highest rates for infection with *Listeria* and *Vibrio*. Case-fatality ratio ranged from 0 percent for *Cyclospora* and *Shigella* to 13 percent for *Listeria* infections. The highest number of deaths was reported among the elderly.[91,92]

In 2011 the CDC released new national estimates for foodborne illnesses acquired in the United States. Data for modeling were gathered through five different surveillance systems and collected during 2000 to 2008.[418] Based on existing data, 31 identified known agents of foodborne disease were estimated to cause 9.4 million illnesses, 55,961 hospitalizations, and 1,351 deaths per year. Viral infections were expected to represent 59 percent of the cases, bacterial infections, 39 percent, and parasites, 2 percent. Norovirus, nontyphoidal *Salmonella*, *Clostridium perfringens*, and *Campylobacter* were estimated to be the pathogens most commonly involved. Norovirus, nontyphoidal *Salmonella*, *Campylobacter*, and *Toxoplasma* were responsible for the most hospitalizations. *Salmonella*, *Toxoplasma*, and *Listeria* accounted for the majority of documented deaths.[418] When modeling included foodborne illnesses caused by unspecified pathogens—either microbes or toxins for which there are no surveillance systems in place or pathogens yet to be discovered—the number of expected foodborne diseases rose to 48 million per year, leading to 128,000 hospitalizations and 3,000 deaths annually.[417]

Clinical manifestations of foodborne disease can affect the gastrointestinal tract and the central nervous system or cause systemic symptoms with little or no intestinal tract involvement. Incubation period and type of consumed food are helpful tools for establishing a presumptive diagnosis.

1. Foodborne diseases with incubation time less than 1 hour are generally caused by chemical poisoning from mushrooms or marine biotoxins, inorganic toxins such as monosodium glutamate (Chinese restaurant syndrome), or metals.
2. Foodborne diseases manifesting as nausea, vomiting, and diarrhea within 1 to 7 hours after food ingestion are normally caused by preformed bacterial toxins, mainly from *Staphylococcus aureus* and *Bacillus cereus*. Biotoxins are less frequently a cause but must be considered in cases of acute onset of neurologic symptoms following seafood or mushroom consumption.

*http://cdc.gov/foodborneburden/surveillance-systems.html

3. Illnesses manifesting as abdominal cramps and diarrhea within a period of 8 to 14 hours are commonly caused by bacteria such as *Clostridium perfringens* or *B. cereus*, through the in vivo production of enterotoxins.
4. Diarrhea, abdominal cramps, and fever with onset in 8 to 48 hours suggest a bacterial etiology. *Campylobacter*, *E. coli*, *Salmonella*, *Shigella*, and *Vibrio parahaemolyticus* are the most common species involved. In the presence of frankly bloody diarrhea, *E. coli* O157, *Shigella*, and *Campylobacter* need to be ruled out.
5. Watery diarrhea presenting more than 15 hours after consumption of suspected food is normally due to viral infections. Noroviruses are the most common foodborne pathogens.
6. Foodborne diseases presenting as diarrhea protracted for days or weeks are normally due to parasites. *Giardia lamblia* and the microsporidia are the most common among children, whereas *Cyclospora* has been described mainly in adults.
7. Some foodborne diseases present as systemic symptoms and longer incubation periods. Examples include typhoid fever, brucellosis, Q fever, toxoplasmosis, tapeworm infection, anisakariasis, and anthrax. *Trichinella* can cause gastrointestinal symptoms in the early phase, but later systemic symptoms prevail. *Listeria* and *Vibrio* spp. can be particularly dangerous in immunosuppressed patients.

Foodborne Disease due to Bacteria, Viruses, and Parasites. Table 44-2 illustrates clinical characteristics and confirmation tests for the diagnosis of common foodborne and waterborne diseases. Detailed guidelines for clinical diagnosis and instructions for collecting stool specimens are available on the CDC website.*

A long list of foods have been associated with enteric infections:

- Unpasteurized milk and dairy products have been associated with salmonellosis and campylobacteriosis and, less frequently, infections with *Brucella* spp., *E. coli*, *L. monocytogenes*, *Mycobacterium* spp., *S. aureus*, *Streptococcus* spp., *Streptobacillus moniliformis*, and *Yersinia enterocolitica*.[295] A nationwide outbreak of *Salmonella enteritidis* gastroenteritis involved 224,000 people in the United States and was associated with ingestion of contaminated ice cream.[209] Mexican-style soft cheese made with unpasteurized milk has been described as source of infection among children.[477] Consumption of raw milk has been associated with a chronic diarrhea syndrome of unknown cause, initially identified in Minnesota and referred to as *Brainerd diarrhea*.[355] Several additional outbreaks have been reported as Brainerd diarrhea, each characterized by watery diarrheal illness of impressively long duration with acute onset and the same constellation of symptoms, including extreme fecal urgency and fecal incontinence. However, despite intensive laboratory examinations, the cause of Brainerd diarrhea remains unknown.[262,312]
- Fresh fruit and vegetables have been linked with a number of pathogens; radish sprouts, lettuce, apple juice, alfalfa sprouts, and spinach have been described as sources of enterohemorrhagic *E. coli*.[73,82] Hot peppers, tomatoes, and cantaloupes have been described as potential sources of *Salmonella*.[76,89]
- Cold salads were described as a vehicle for *Shigella* and *Listeria* infection.[32] Homemade canned food can be associated with *Clostridium botulinum* infection in adults[438]; honey is associated with *Botulinum* intoxication in infants.
- Poultry, especially raw chicken, and eggs have been identified as sources of foodborne infection due to *Campylobacter* and *Salmonella*.[108]
- Pork and chitterlings have been associated with *Yersinia* infection.[80]
- Ingestion of raw fish (sushi or sashimi) has led to infection with *Vibrio parahaemolyticus* and various parasites.[118,295] *V. parahaemolyticus* outbreaks have

TABLE 44-2 **Foodborne Disease Agents and Clinical Presentation**

Usual Incubation Periods	Causative Agent	Clinical Illness			Epidemiologic and Laboratory Diagnosis
		Fever	Diarrhea	Vomiting	
5 min-6 hr (usually <3 hr)	Chemical or toxin—see Tables 44-2 and 44-3	Rare	Occasional (see Table 44-3)	Common	Demonstration of toxin or chemical from food or epidemiologic incrimination of food
1-6 hr (usually <1 hr)	*Staphylococcus aureus* enterotoxin	Rare	Occasional	Profuse	Isolation of organisms in food (>10^5/g)/vomitus/ stool; detection of enteroxin in food
	Bacillus cereus emetic toxin	Rare	Occasional	Profuse	Isolation of organisms in food (>10^5/g)/vomitus/ stool
6-24 hr	*Clostridium perfringens* enterotoxin	Rare	Typical	Occasional	Isolation of organisms or toxin from food (>g) or stools of ill persons, epidemiologic incrimination of food; detection of enteroxin in food
	B. cereus enterotoxin	Rare	Typical	Occasional	

TABLE 44-2 **Foodborne Disease Agents and Clinical Presentation** (Continued)

Usual Incubation Periods	Causative Agent	Clinical Illness			Epidemiologic and Laboratory Diagnosis
		Fever	Diarrhea	Vomiting	
12-72 hr	*Clostridium botulinum*	Clinical syndrome compatible with botulism	Constipation more common		Isolation of organism or toxin from food (10^5/g) or stools; demonstration of toxin in serum or food
16-96 hr	*Shigella*	Common	Typical, often bloody	Occasional	Isolation of organism from clinical specimens from two or more ill persons; isolation of organism from epidemiologically implicated food
	Nontyphoidal *Salmonella*	Common	Typical	Occasional	
	Enteroinvasive *E. coli* (EIEC)	Common	Typical, may be bloody	Occasional	
	Enteropathogenic *E. coli* (EPEC)	Occasional	Typical	Occasional	
	Enterotoxigenic *E. coli* (ETEC)	Rare	Typical	Rare	
	Vibrio parahaemolyticus; V. cholerae enterotoxin	Occasional	Typical	Occasional	
1-3 days	Caliciviruses (noroviruses) Rotavirus	Occasional	Typical	Common	Antigen detection (enzyme immunoassay) in stool; immune electron microscopy of stool; detection of viral RNA in stool or vomitus by PCR
1-10 days	*Yersinia*	Uncommon	Typical, severe abdominal pain	Uncommon	Isolation of organisms from food or clinical specimens of ill persons
2-10 days	*Campylobacter jejuni*	Common	Typical, often bloody	Uncommon	Isolation of organisms from food or clinical specimens of ill persons
1-11 days	*Cryptosporidium*	Occasional	Common	Occasional	Demonstration of oocysts in stool or in small bowel biopsy of ill persons; demonstration of organism in epidemiologically implicated food
	Cyclospora	Occasional	Common	Occasional	Demonstration of parasite in stool or in small bowel biopsy of ill persons; demonstration of organism in epidemiologically implicated food
	Giardia intestinalis	Occasional	Common	Occasional	Demonstration of parasite in stool or in small bowel biopsy of ill persons; demonstration of organism in epidemiologically implicated food
2 days-weeks	*Bacillus anthracis*	Common	Typical	Frequent	Isolation of organism from blood or contaminated meat
1-7 days	*E. coli* O157:H7 and other Shiga toxin–producing *E. coli*	Uncommon	Typical	Frequent	Isolation of organism from food or stool or identification of toxin in stools of ill persons
3-60 days, usually 7-14	*Salmonella typhi*	Common	Diarrhea or constipation	Uncommon	Isolation of organisms from food or clinical specimens of ill persons
7-21 days	*Brucella* spp.	Common	Common	Rare	Isolation of organisms from blood or bone marrow culture of ill persons; fourfold increase in standard agglutination titer overall several weeks or single titer 1:160 in person with compatible clinical syndrome
1-4 wk	*Giardia lamblia*	Rare	Common	Rare	Stool for ova and parasite examination enzyme immunoassay
2 days-8 wk	*Trichinella spiralis*	Common	Common	Common	Serology, muscle biopsy

TABLE 44-3 **Fungal and Inorganic Toxins: Food Poisoning**

Type of Chemical, Toxin, or Poison	Food	Clinical Symptoms	Onset of Symptoms (hr)
Heavy metals*	Water (through metallic container) and food	Gastrointestinal	1
Monosodium glutamate	Chinese food	Burning sensation, heavy feeling in chest, pressure over face, flushing, gastrointestinal	1
Ibotenic acid, muscimol	Mushroom	CNS: confusion, delirium, visual disturbances, lethargy	2
Coprine	Mushroom	Disulfiram-like effect: nausea, vomiting, headache, hypotension, flushing, paresthesia, and tachycardia	2
Muscarine	Mushroom	Parasympathetic: sweating, salivation, lacrimation, blurred vision, diarrhea, bradycardia, hypotension	2
Psilocybin, psilocin	Mushroom	CNS: hallucinations, anxiety, mood elevation, weakness	2
Diverse, mostly unknown	Mushroom	Gastrointestinal	2
Monomethylhydrazine, gyromitrin	Mushroom	Cellular destruction, gastrointestinal, loss of coordination, convulsion, coma, death	6-12
Amatoxins, phallotoxins	Mushroom	Cellular destruction, gastrointestinal, hepatic and renal necrosis	6-24
Vomitoxin (deoxynivalenol)	Cereals contaminated with *Fusarium* species	Vomiting acutely Altered mucosal immunity with chronic exposure	<3

CNS, central nervous system.
*Includes antimony, arsenic, cadmium, copper, mercury, thallium, tin, and zinc.

been also associated with raw oysters and clams from Northeastern and Pacific Northwestern coasts of the United States.[85] Parasites acquired through ingestion of raw fish include larval nematodes of the family Anisakidae, fish tapeworm of the species *Diphyllobothrium*, the fluke *Nanophyetus salmincola* from salmon, and many other helminths.[330]

- Consumption of raw and lightly cooked shellfish (mussels, clams, oysters, lobsters, and other mollusks) is associated with infection by agents that are native to the marine environment or released by sewage effluents contaminating environmental waters. Viruses such as caliciviruses and hepatitis A virus are commonly concentrated and transmitted through shellfish.[323] The *Vibrio* genus (specifically *V. vulnificus*), acquired either by eating shellfish or by contaminating open wounds by swimming, presents a serious problem in terms of the severity of human illness and death, especially in people with liver disease.[221,333]

Food Poisoning by Chemicals. Intoxication from seafood is caused by toxins accumulated in fish, shellfish, and crustaceans. Marine toxins are tasteless and odorless and are not inactivated by cooking: once ingested they normally cause symptoms within a few hours. Symptoms can be gastrointestinal, neurologic, or systemic. Clinical characteristics of shellfish poisoning are listed in Table 44-3. Prevention of such illness is accomplished by monitoring of toxin concentration in seafood samples.[437] Scombroid fish poisoning is caused by inadequate conservation of certain types of fish. If fish are not adequately refrigerated after being caught, marine bacteria proliferate and catalyze decarboxylation of fish tissue histidine into histamine; once the fish is consumed, patients present with symptoms of histamine toxicity. A large reported outbreak in the United States was associated with escolar fish. Puffer fish syndrome is a lethal intoxication resulting from consumption of certain specific species of puffer. It is very rare in the United States but more common in Japan.[437]

Chinese restaurant syndrome appears to be caused by excessive amounts of monosodium glutamate in foods. Symptoms include paresthesias, reversal of hot-cold sensations, loss of proprioception, flushing, weakness, and burning sensations.

Mushrooms toxins produce several clinical syndromes, generally within 2 hours of ingestion (Table 44-4),[202] except for poisoning caused by amatoxins, phallotoxins, amantin, monomethylhydrazine, and gyromitrin, which may produce symptoms, including death, up to 24 hours after ingestion.[202]

Heavy metals, such as antimony, arsenic, cadmium, copper, mercury, thallium, tin, and zinc, cause irritation of the gastric mucosa, with nausea, vomiting, and abdominal cramps, which usually resolves 2 to 3 hours after the offending agent has been removed.[19,75]

Prevention of Foodborne Disease. Changes in human behavior, increased consumption of ready-to-eat food, centralization of food production, processing, and distribution, and globalization of food market are all risk factors for foodborne disease. Among outbreaks reported from 1998 through 2002, 46 percent were associated with at least one pitfall in the food chain process.[295,505] Major risk factors for food contamination were food handling by a person infected or colonized by a pathogen, bare-handed contact with food, inadequate cleaning of preparation equipment or utensils, and cross contamination from a raw ingredient of animal origin. Factors associated

TABLE 44-4 **Marine Biotoxins**

Syndrome	Symptoms	Incubation period	Toxin	Mechanism of Action	Food Source	Geographic Distribution	Seasonality
Paralytic shellfish poisoning	Facial and perioral paresthesias, headache, muscular weakness, mental status changes, nausea, vomiting, death	30 min-4 hr	Saxitoxin	Blocks sodium channels	Shellfish	NW and NW United States, Chile, Japan	May-Nov
Diarrheic shellfish poisoning	Diarrhea, nausea, vomiting, abdominal pain, chills	30 min-12 hr	Okadaic acid	Inhibits protein phosphatase	Shellfish	Japan, Europe, Africa	
Amnesic shellfish poisoning	Nausea vomiting, abdominal cramps, diarrhea, headache, visual disturbance, anterograde amnesia, confusion, coma	15 min-6 hr	Domoic acid	Stimulates glutamate receptors	Shellfish	Canada, NE and NW United States	
Neurotoxic shellfish poisoning	Paresthesia, abdominal pain, dizziness, diplopia, gait disturbance, reversed temperature perception, respiratory difficulty	5 min-4 hr	Brevetoxins	Opens sodium channels	Shellfish and other fish	Western Florida, Caribbean	Spring-fall
Ciguatera	Nausea, vomiting, abdominal cramps, facial and perioral paresthesias, headache, reverse temperature perception, extremity pain, arthralgia, myalgia, sharp pain in the legs and teeth	1-6 hr	Ciguatoxin, maitotoxine	Opens Na^+ channels; opens Ca^{2+} channels	Predatory fish reef	Tropical areas	February-September
Scombroid fish poisoning	Pruritic rash, flushing, sweating, perioral tingling, dizziness, facial and lingual swelling, vomiting, diarrhea, urticaria, bronchospasm	Minutes-hours	Histamine	Histamine receptors	Tuna, mahi-mahi, mackerei, sardines	Worldwide	Year-round
Puffer fish	Facial paresthesia, ascending paralysis, respiratory failure, circulatory collapse, death	30 min-3 hr	Tetrodotoxin, saxitoxin	Blocks Na^+ channels	Puffer fish	East Asia	

with bacterial proliferation in food include inadequate refrigeration, slow cooking, insufficient time or temperature during hot holding, or long delay between food preparation and consumption.

Detailed description regarding safe food processing can be retrieved on the website of the U.S. Department of Agriculture (USDA) and other websites.*

Waterborne Disease. The waterborne disease and outbreak surveillance system in the United States is responsible for collecting data and reporting on waterborne disease. The database collects information on outbreaks associated with recreational water, drinking water, and water not intended for drinking. During 2007 to 2008, 36 outbreaks associated with drinking water were reported: of those, 61 percent manifested as acute gastrointestinal illnesses and 3 percent as hepatitis; the remainder were either associated with respiratory symptoms or skin irritation. Bacterial agents accounted for 41 percent of acute gastrointestinal disease outbreaks: *Campylobacter* spp., *E. coli* O157:H7, *Salmonella* spp., and *Providencia* were identified as etiologic agents. Viruses (norovirus and hepatitis A) were responsible for 18 percent of outbreaks, and parasites (*Cyclospora cayetanensis* and *Giardia intestinalis*) were the cause of 13.6 percent. The remaining outbreaks were either caused by unknown agents or multiple agents. More than half of the outbreaks were associated with untreated or inadequately treated ground water.[63] During the same period (2007-2008) a total of 134 recreational-water outbreaks were reported: 86 percent of outbreaks involved treated recreational water, and the remainder involved untreated fresh or marine water. Sixty percent of outbreaks manifested as acute gastrointestinal illness, with the remainder as respiratory or dermatologic disease. *Cryptosporidium* was responsible for 74 percent of the waterborne diseases presenting as gastrointestinal symptoms, followed by norovirus (6%), *Shigella* (4.9%), *Giardia* (3.7%), *E. coli* O157:7 (3.7%), and *Plesiomonas shigelloides* (1.2%).[232]

CLINICAL CLASSIFICATION OF DIARRHEAL EPISODES

Diarrhea in children can be classified in several ways. Based on duration, diarrhea can be acute (usually self-limited and lasting <7 days), prolonged (7 to 14 days), persistent (>14 days), or chronic (usually more than 30 days or relapsing).[318] The importance of this classification is that, in addition to focusing on the importance of subsequent development of undernutrition,[319] it can help to identify the most likely causes. Acute diarrhea can be associated with many bacterial and viral pathogens, whereas prolonged and persistent diarrhea is associated with parasites, especially *Giardia duodenalis*, *Cryptosporidium*, and other coccidia, and some bacterial pathogens including enteroaggregative *E. coli* (EAEC) and enteropathogenic *E. coli* (EPEC).[319,334,345,348,467] On the other hand, chronic diarrhea, although it can start as an infectious diarrhea, is often the result of a postinfectious process (e.g., malabsorption, irritable bowel syndrome, inflammatory bowel disease).[508]

Diarrhea can also be classified as inflammatory or noninflammatory and as osmotic or secretory, based on its pathogenesis. Inflammatory diarrhea can be defined by the presence of abundant leukocytes in the stools or by measuring other markers of inflammation such as fecal lactoferrin.[231,352,475] Inflammatory diarrhea is associated with "invasive" bacterial pathogens such as *Shigella*, *Salmonella*, and *Campylobacter;* therefore, identifying this type of diarrhea can help raise suspicion of these agents. On the other hand, osmotic diarrhea is important in young children. Because rotavirus, the most common cause of diarrhea in young children worldwide, can be associated with accumulation of carbohydrates in the intestinal lumen and malabsorption, measurement of reducing substance in stool may be helpful in resource-limited situations to aid in its diagnosis.[293]

Finally, diarrhea can be classified by its characteristics as watery or dysenteric. Watery diarrhea is characterized by liquid or semi-liquid stools, usually of large volume, with or without fever, vomiting, and abdominal pain. This type of diarrhea can be associated with any type of viral, bacterial, or parasitic agents. However, dysentery, a syndrome characterized by fever, abdominal cramps, and tenesmus with small, frequent bloody stools, sometimes with mucus (colitis or colonic inflammation), is associated with a narrower list of pathogens, including *Shigella*, *Salmonella*, *Campylobacter*, Shiga toxin–producing *E. coli* (STEC), enteroinvasive *E. coli* (EIEC), *Yersinia*, *Clostridium*, and some parasites—*Entamoeba histolytica*, *Strongyloides*, and *Balantidium coli*. Recognition of this syndrome affects both diagnostic evaluation and empirical therapy.[370]

ORGANISMS THAT CAUSE DIARRHEA

Many viral, bacterial, and parasitic organisms produce diarrhea in children. The major enteric pathogens associated with infectious diarrhea are shown in Table 44-5.[102]

Viruses

Acute infectious diarrhea of viral origin generally is a self-limited disease characterized by various combinations of diarrhea, nausea, vomiting, abdominal cramps, headaches, myalgias, and low-grade fever.[313,339,461] Bowel movements are watery and generally do not contain mucus or blood. Vomiting is the most common manifestation of this condition. Rotavirus, norovirus, enteric adenovirus, and astrovirus are common causes of viral gastroenteritis.[121,388] Other viruses, including coronaviruses, Breda virus, parvoviruses, pestiviruses, picobirnaviruses, and toroviruses, have been linked to gastroenteritis in humans with varying degrees of certainty.[40,269,507]

Rotaviruses

Worldwide, rotavirus is the leading cause of severe gastroenteritis in children. Rotavirus is responsible for the deaths of nearly 450,000 children younger than 5 years

TABLE 44-5 **Pathogens Associated with Infectious Diarrhea in Children**[102]

Type	Enteropathogen	Clinical and Epidemiologic Characteristics
Virus	Rotavirus	Acute watery dehydrating diarrhea with vomiting and fever, particularly in young children during winter
	Norovirus	Acute watery diarrhea with vomiting; short duration; most common cause of outbreaks of nonbacterial gastroenteritis worldwide
	Astrovirus	Short duration mild watery diarrhea with fever and vomiting in young children
	Enteric adenovirus	Mild watery diarrhea with vomiting and low-grade fever in young children; serotypes 40 and 41
Bacteria	*Shigella*	Severe diarrhea, often dysenteric with fever; high risk of person-to-person transmission
	Salmonella	Acute watery diarrhea, occasionally dysenteric, and systemic infections; exposure to carriers, food, and animals (poultry, reptiles)
	Campylobacter	Acute watery diarrhea, often dysenteric with fever; food and animal exposure (poultry)
	Shiga toxin–producing *E. coli*	Watery diarrhea progressing to blood streaked or grossly bloody diarrhea usually without fever; some serotypes are associated with hemolytic-uremic syndrome; food exposure, person-to-person spread, water, and contact with animals[102]
	Other diarrheagenic *E. coli*	Watery diarrhea; some pathotypes with bloody diarrhea (EIEC); usually acute; some pathotypes with prolonged diarrhea (EAEC, EPEC); food exposure[102]
	Vibrio cholerae	Acute watery dehydrating diarrhea in endemic regions; food or water exposure
	Vibrio parahaemolyticus	Watery diarrhea, often dysenteric; seafood related
	Yersinia enterocolitica	Acute watery diarrhea, may cause fever, dysentery and pseudoappendicitis; most common in northern countries; food or animal exposure (swine)
	Aeromonas hydrophila	Acute watery diarrhea; water, food, or animal exposure
	Plesiomonas shigelloides	Acute watery diarrhea; water, fish, or animal exposure
	Clostridium difficile	Diarrhea often with fever and blood after administration of antimicrobial agents
	Clostridium perfringens	Foodborne outbreaks; short-duration acute watery diarrhea with abdominal pain and fever
	Staphylococcus aureus	Foodborne outbreaks; short-duration vomiting sometimes with diarrhea
	Bacillus cereus	Foodborne outbreaks; two distinct short-duration illnesses: emetic and diarrheal
	Listeria monocytogenes	Foodborne outbreaks; systemic infection or acute watery diarrhea, often with fever
Parasite	*Entamoeba histolytica*	Watery or bloody diarrhea (amebic dysentery) with fever and abdominal pain; hepatic amebiasis
	Giardia	Watery diarrhea; usually persistent or chronic diarrhea; food or water exposure
	Cryptosporidium	Watery diarrhea; usually persistent; severe diarrhea in patients with AIDS; food or water exposure; outbreaks
	Isospora belli	Watery diarrhea, usually persistent; severe diarrhea in patients with AIDS; food or water exposure
	Cyclospora	Watery diarrhea, usually persistent; severe in young children; food or water exposure
	Microsporidia	Watery diarrhea; usually persistent; severe diarrhea in patients with AIDS; food or water exposure
	Strongyloides	Watery diarrhea, often with mucus, blood, abdominal pain, and eosinophilia; hyperinfection syndrome

of age each year, mainly in developing countries.[357,457] Rotavirus gastroenteritis affects more than 90 percent of children by the time they are 3 years of age and may cause moderate to severe vomiting that precedes diarrhea. It accounts for 10 to 50 percent of the cases of diarrhea in children and is the most common cause of diarrhea in infants and children during winter months in colder climates. Rotavirus accounts for 35 to 50 percent of infants and young children hospitalized for acute diarrhea. Stools usually are watery or soft, and the presence of blood or leukocytes is rare. Asymptomatic rotavirus infections occur frequently,[339,374] and reinfection appears to be a common event.[473,474] The mechanism of spread is fecal-oral. Shedding of virus most frequently occurs from a few days before to 10 days after the onset of illness.[374]

Natural rotavirus infection efficiently protects against severe disease associated with reinfection. Two virus surface proteins with antigenic properties, VP4 and VP7, are found in various conformations and are the basis for a binary serologic classification scheme that defines the G/P type of the virus[21,365] (Fig. 44-1). Five genotypes (G1 to G4, and G9) accounted for 88 percent of all strains, although extensive geographic and temporal differences exist.[34]

The first rotavirus vaccine licensed in the United States was associated with an increased rate of intussusception, resulting in its withdrawal from the market within 14 months of being licensed.[325,391] Two new vaccines have recently been shown to be safe and effective in protecting young children against severe rotavirus gastroenteritis and are now marketed worldwide.[400,476] Rotavirus vaccines have reduced the health burden of rotavirus gastroenteritis in both developed and developing countries.[122,393]

Noroviruses

Noroviruses are in the family Caliciviridae and have been identified as the second most common viral cause of severe gastroenteritis in children younger than 5 years of age in developing and developed countries, preceded only by rotavirus.[175] Norovirus is considered the most

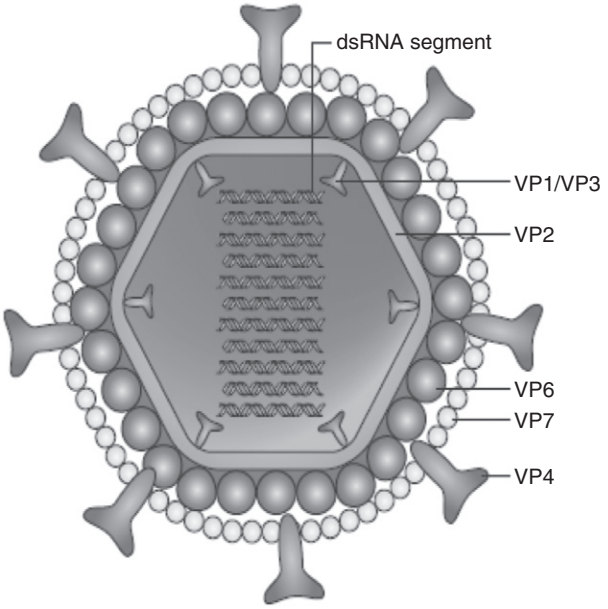

FIGURE 44-1 ■ Rotavirus: schematic representation of a virion. VP4 and VP7, two virus surface proteins, are the basis for the serologic classification of the virus. (See companion website on Expert Consult for a color version of this figure.) (From Angel J, Franco MA, Greenberg HB. Rotavirus vaccines recent developments and future considerations. *Nat Rev Microbiol* 2007;**5**:529–39.)

common cause of outbreaks of nonbacterial gastroenteritis worldwide.[50,302,472,511] It accounts for 12 percent of severe gastroenteritis cases among children younger than 5 years of age and 12 percent of mild and moderate diarrhea cases among persons of all ages.[362] It is estimated that each year norovirus causes 64,000 episodes of diarrhea requiring hospitalization, 900,000 clinic visits among children in industrialized countries, and up to 200,000 deaths of children younger than 5 years of age in developing countries.[362] The mean incubation period for norovirus is 24 to 48 hours. The primary routes of transmission are fecal-oral, including consumption of fecally contaminated food or water; direct person-to-person contact, especially in schools, childcare centers, restaurants, summer camps, hospitals, nursing homes, and cruise ships*; and through contaminated objects or environments. A low inoculum dose is required for infection.[460] Clinical manifestations include acute onset of vomiting, nonbloody diarrhea, or both lasting 12 to 60 hours.[175] The identification of human histo-blood group antigens as norovirus receptors opens a new approach for evaluation of susceptibility and therapy of norovirus infection.[150,175,454]

Noroviruses are genetically and antigenically diverse. Molecular epidemiology techniques have identified substantial diversity in strains, indicating that epidemic strains might be more virulent or more environmentally persistent than nonepidemic strains.[50] Five genogroups (G) and several subgenogroups have been assigned. Strains of three genogroups GI, GII, and GIV are found in humans; genogroups GI and GII are the more frequently found, with GII most prevalent worldwide.[302,509,510]

*References 5, 77, 241, 242, 268, 389.

Astroviruses

Astrovirus gastroenteritis occurs worldwide and has been associated with outbreaks of mild gastroenteritis in schools, daycare centers, pediatric wards, and nursing homes.[124,174,193,214,313] Illness is restricted primarily to children younger than the age of 2 years, elderly people, and immunocompromised individuals.[239,324] Astrovirus infections can be asymptomatic[308] and associated with other enteric viruses.[394] Eighty percent or more of adults have antibodies against the virus. The incubation period is 2 to 4 days.[174,239] Symptoms include fever and malaise, followed by watery diarrhea that may last approximately 3 days. Vomiting is an uncommon symptom. Short-term intolerance of monosaccharides and more prolonged intolerance of cow's milk protein have been reported after astrovirus infection.[174] Until 2008, eight different antigenic types were described in humans, but recently new species have been found in stool samples from patients suffering gastroenteritis.[152-154,255] The virus can be detected by electron microscopy or by more specific molecular tools such as reverse transcriptase–PCR (RT-PCR).[174,239,481]

Enteric Adenoviruses

Human adenoviruses of subgroups A to F have been identified as etiologic agents in a wide range of human diseases, including conjunctivitis, upper respiratory tract infections, and pneumonia. A subgroup of fastidious adenoviruses (group F) with a distinct set of antigenic determinants and specific tissue culture growth characteristics has been shown to be associated with acute gastroenteritis and is referred to as enteric adenovirus.[59,274,470] The enteric adenoviruses in group F include serotypes 40 and 41,[274] which are responsible for approximately 5 percent of cases of endemic pediatric diarrhea worldwide,[127,430-432] with higher prevalence in children younger than age 24 months.[127] The clinical manifestations include watery diarrhea accompanied by vomiting, low-grade fever, and mild dehydration.[274] Antibody prevalence to enteric adenovirus increases from 20 percent during the first 6 months of life to 50 percent or greater by the third or fourth year of life.[433] Seasonal shifts in the predominance of types 40 and 41, similar to those described for rotavirus, may occur.[59] Infection with enteric adenovirus appears to increase in the summer, although with a less marked seasonal variation than that exhibited by rotavirus, which peaks in the winter.[59] Outbreaks of enteric adenovirus diarrhea have been described in childcare centers, where asymptomatic excretion is a common occurrence.[470,483]

Bacteria

Shigella

Shigella is the principal cause of clinical dysentery and an important cause of morbidity and mortality among children in impoverished regions of the developing world.[270] In the United States, shigellosis is the third most frequent FoodNet pathogen in sentinel states but appears to be

decreasing in incidence. There are four serogroups of *Shigella*, containing 46 serotypes: *S. dysenteriae*, *S. flexneri*, *S. boydii*, and *S. sonnei*. In developing countries *S. flexneri* is the predominant species, whereas *S. sonnei* predominates in industrialized regions. Infection by *Shigella* spp. rarely occurs in the first few months of life but is a common occurrence in children between the ages of 6 months and 10 years.[88] In highly endemic areas, peak infection rates occur in the second year of life. Children infected with *Shigella* can have asymptomatic excretion, watery diarrhea, or dysentery. Hemolytic-uremic syndrome may occur after infection with Shiga toxin 1 (Stx1)–producing strains (primarily *S. dysenteriae* serotype 1). The postinfectious complications include reactive arthritis[464] and postinfectious irritable bowel syndrome.[198] Shigellosis results from the exposure to low inoculums of the bacteria; in addition to person-to-person spread, shigellae can be transmitted through contaminated foods, sexual contact, and water used for drinking or recreational purposes.[142,295] Mild symptoms are self-limiting but, in more severe cases, antibiotics are recommended for cure and preventing relapse. The progressive development of antibiotic resistance in *Shigella* isolates is a worldwide problem.[270]

Salmonella

Salmonella infections are associated with several clinical syndromes: asymptomatic carriage, acute gastroenteritis, bacteremia, enteric fever, and dissemination with localized suppuration, such as abscess, osteomyelitis, or meningitis.[96,406] Identification of *Salmonella* spp. in the laboratory is not difficult, but the various terminologies used to classify *Salmonella* spp. are confusing. Based on the current classification, the genus *Salmonella* contains only two species, *S. bongori* and *S. enterica*, but there are more than 2500 serovars of *S. enterica*. *S. enterica* serovar typhi *(S. typhi)* and nontyphoidal salmonellae (NTS) are important causes of infection and disease in children. Typhoid fever is particularly common in South and South East Asia and is estimated to cause more than half a million deaths each year. NTS are a major cause of foodborne infections including gastroenteritis worldwide.[20,182,187] In the United States, in the past decade, the *Salmonella* isolates most frequently reported have been *S. enterica* serotype *typhimurium* and *S. enterica* serotype *enteritidis*.[78,88]

Salmonella gastroenteritis occurs most commonly in the first 5 years of life, decreases in frequency during childhood, and remains relatively constant throughout the adult years.[88] Although most episodes of *Salmonella* infection are foodborne, reptiles, including turtles, snakes, lizards, and iguanas, carry certain serotypes of *Salmonella* in their intestinal tracts and have been associated with episodes of salmonellosis.[376,445] Numerous outbreaks of disease caused by *Salmonella* after ingestion of contaminated food products, including eggs, milk, ice cream, peanut butter, and fresh produce, have been reported.* Foodborne outbreaks associated with *Salmonella* have been reported from fairs or festivals, hospitals, nursing homes, and prisons.[88]

Campylobacter

Campylobacter spp. are recognized as among the most important causes of acute diarrheal disease in humans throughout the world,[12,67,243] including the United States.[12,87] The organism is a microaerophilic, curved gram-negative rod, carried in the intestine of many wild and domestic animals, particularly avian species including poultry. Healthy animals may be intestinal carriers.[435] Water can be a direct source of human infection, although food contamination from food-producing animals is a more significant problem. The main risk factors for *Campylobacter* infection are age younger than 5 years and age 20 to 29 years; male sex; handling and consumption of raw or undercooked poultry and other meats; consumption of unpasteurized milk and dairy products and untreated water; and contact with pets and farm animals.[163] Most *C. jejuni* diarrheal illness in the United States is foodborne.[295]

Currently, 20 *Campylobacter* spp. and subspecies are recognized.[435] *C. jejuni* and *C. coli* are the two predominant species, although use of selective media and failure to use stool filtration techniques may preclude isolation of other *Campylobacter* spp. Many clinical microbiology laboratories do not differentiate *C. jejuni* and *C. coli*. Emerging *Campylobacter* spp. have also been associated with a range of gastrointestinal diseases, particularly gastroenteritis, inflammatory bowel disease, and periodontitis.[298] People infected with *C. jejuni* may develop diarrhea, cramping abdominal pain, chills, and fever. Gross rectal bleeding may occur, and mucus and fecal leukocytes may be present, resembling the illness produced by *Shigella*. The clinical presentation also may mimic that of inflammatory bowel disease. *Campylobacter fetus*, recognized as a cause of fever, bacteremia, and meningitis in immunocompromised hosts and of abortion, rarely causes diarrhea. *C. jejuni* has been associated with reactive arthritis and Guillain-Barré syndrome.[379,380]

Diarrheagenic Escherichia coli

E. coli associated with diarrhea is referred to as diarrheagenic *E. coli*.[328] There are six well-described categories of diarrheagenic *E. coli*, classified based on clinical, microbiologic, and epidemiologic characteristics. Current classification is based mainly on the identification of specific virulence genes associated with each pathotype (Table 44-6).[254,328] In children, diarrheagenic *E. coli* as a group are responsible for 30 to 40 percent of all diarrhea cases worldwide.[342,343,347,354]

8. Shiga toxin–producing *E. coli* (STEC), also referred to as enterohemorrhagic *E. coli* (EHEC) or verotoxin-producing *E. coli* (VTEC), is probably the most important pathogen in this group, owing to its association with hemolytic-uremic syndrome. STEC produces a spectrum of disease, from mild watery diarrhea, to afebrile bloody diarrhea, hemorrhagic colitis, and hemolytic-uremic syndrome.[254,307] Only a small proportion (5% to 10%)

*References 55, 76, 89, 209, 295, 384.

TABLE 44-6 **Diarrheagenic *E. coli* Pathotypes**

Name	Abbreviation	Clinical and Epidemiologic Characteristics	Diagnosis
Shiga toxin-producing or enterohemorrhagic or verotoxin-producing *E. coli*	STEC or EHEC or VTEC	Watery diarrhea progressing to bloody diarrhea usually without fever; may develop hemolytic-uremic syndrome (5%-10%), especially in children <5 years, associated with specific strains including both O157 and non-O157 serotypes; food exposure, person-to-person spread, water, and contact with animals; important reservoir in cattle	Simultaneous culture for O157 STEC and non–culture assay for Shiga toxin: stool culture on sorbitol-MacConkey media to detect sorbitol-nonfermenting *E. coli* O157; detection of Shiga toxins on stool sample by enzyme immunoassays; detection of Shiga toxin genes (*stx1* and *stx2*) and intimin gene (*eae*) by PCR
Enteropathogenic *E. coli*	EPEC	Acute watery diarrhea; may cause prolonged or persistent diarrhea in young children in developing countries; associated with hospital nursery outbreaks; atypical strains (aEPEC) are more prevalent than typical strains (tEPEC) worldwide	Detection of intimin gene (*eae*) ± bundle-forming pili (*bfp*A) by PCR and absence of Shiga toxins; HEp-2 cells adherence assay and serotyping have been replaced by molecular methods; serotyping should be performed only for research or outbreak investigations.
Enterotoxigenic *E. coli*	ETEC	Acute watery dehydrating diarrhea; usually self-limited; important cause of diarrhea in young children in developing countries and most important cause of traveler's diarrhea	Detection of enterotoxins: heat-labile (LT) and heat-stable (ST) by enzyme immunoassays or PCR
Enteroaggregative *E. coli*	EAEC	Acute watery diarrhea; may cause prolonged or persistent diarrhea in young children in developing countries and in HIV-infected patients; second most important cause of traveler's diarrhea	Detection of the *agg*R regulatory gene and other virulence genes: *aap, aat*A, *ast*A by PCR. Characteristic "stacked-brick" attachment patterns on HEp-2 cells, used only in research laboratories
Enteroinvasive *E. coli*	EIEC	Acute watery diarrhea, usually dysenteric; *Shigella*-like pediatric diarrhea; an occasional cause of foodborne outbreaks in industrialized areas	Detection of invasion plasmid antigen of *Shigella* (*ipa*H) by PCR
Diffusely adherent *E. coli*	DAEC	Acute watery diarrhea, particularly in children >12 mo of age in developing countries; may be an important cause of childhood diarrhea in the United States	Detection of Dr adhesins (*daa*D) or Dr-associated genes by PCR; characteristic "diffuse" attachment patterns in HEp-2 cells, used only in research laboratories

PCR, polymerase chain reaction.

of children infected with STEC, usually younger than 5 years of age, develop hemolytic-uremic syndrome.[292] This syndrome is characterized by the triad of hemolytic anemia, thrombocytopenia, and renal insufficiency and is associated most frequently with *E. coli* O157:H7. However, strains of many other serotypes are also associated with hemolytic-uremic syndrome. For example, the large European outbreak that began in Germany in 2011 was produced by an O104:H4 strain.[161] STEC has two potent cytotoxins encoded by lambdoid bacteriophages: Shiga toxin 1 (Stx1, also called verotoxin 1) and Stx2 (or verotoxin 2). Multiple variants of Stx2 exist, as well as several uncommon variants of Stx1. Sxt1 is identical to Shiga toxin made by *S. dysenteriae* type 1.[244,307] These strains usually possess genes like those found in EPEC (see later) for colonizing the gut, although the recent O104:H4 strain had colonization genes like those of EAEC (see later).[62] Many STEC strains appear to be nonvirulent for humans. Most reported outbreaks result after ingestion of contaminated food or water, although person-to-person transmission is also important, particularly in families and daycare settings. Healthy cattle harbor the organism as part of their intestinal flora and are the main animal reservoir for STEC. Direct transmission from animals and their environments to humans in public settings where children come in contact with farm animals, such as petting zoos, represents a public health concern.[376] The diagnosis of STEC is based on the identification of Shiga toxin by immunoassays or PCR or isolation of pathogenic STEC strains.[185,211]

9. Enteropathogenic *E. coli* (EPEC) is associated with both sporadic and epidemic diarrhea in children, especially in developing countries.[131,254] EPEC most commonly causes acute diarrhea and may also cause persistent diarrhea in young children. EPEC was originally serogroup-defined as *E. coli* associated with infantile diarrhea. Subsequently, it was defined by its characteristic localized adherence pattern in tissue cultured cells. Currently, it is identified

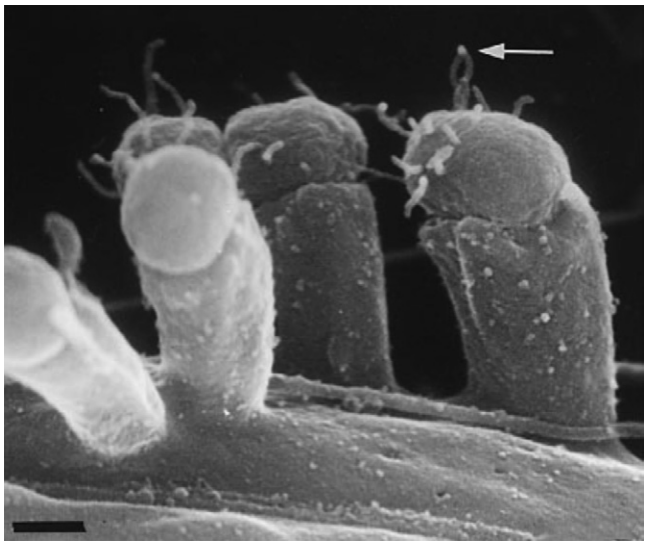

FIGURE 44-2 ■ Enteropathogenic *E. coli* (EPEC): intimate attachment of bacteria to the epithelial surface and effacement of host cell microvilli (pedestal formation lesion). (From Knutton S, Rosenshine I, Pallen MJ, et al. A novel EspA-associated surface organelle of enteropathogenic *Escherichia coli* involved in protein translocation into epithelial cells. *EMBO J* 1998;**17**:2166–76.)

mainly based on the presence of a specific virulence gene *(eae)*.[341] EPEC induces a distinctive histopathology known as the "attaching and effacing" lesion, which is characterized by the intimate attachment of bacteria to the epithelial surface and effacement of host cell microvilli (Fig. 44-2).[131] EPEC is currently divided into two groups, typical EPEC (tEPEC) and atypical EPEC (aEPEC), based on the presence of the EPEC adherence factor plasmid, which is only found in tEPEC. Recent epidemiologic studies indicate that aEPEC is more prevalent than tEPEC in both developed and developing countries.[341] However, the large variety of serotypes and genetic virulence properties of aEPEC strains makes it difficult to determine which strains are truly pathogenic.[212]

10. Enterotoxigenic *E. coli* (ETEC) is an important cause of diarrhea in infants and children living in developing countries and is the most important bacterial agent of traveler's diarrhea.[254,386,448] ETEC causes watery diarrhea, which can be a mild, self-limited disease or severe dehydrating diarrhea. ETEC colonizes the small bowel mucosa and elaborates enterotoxins, which gives rise to intestinal secretion. Colonization is mediated by one or more colonization factors (CFs). ETEC strains express heat-labile (LT) and/or heat-stable (ST) enterotoxins. LT is closely related in structure and function to cholera enterotoxin (CT) expressed by *Vibrio cholerae*.[448]
11. Enteroinvasive *E. coli* (EIEC) is related antigenically and biochemically to *Shigella* and causes either a dysentery-like illness or watery diarrhea. EIEC is distinguished from *Shigella* by a few minor biochemical tests, but these pathotypes share essential virulence factors.[254] EIEC infection is thought to represent an inflammatory colitis, although many patients seem to manifest a secretory, small bowel syndrome. Infections generally occur in adults; foodborne outbreaks have been reported.
12. Enteroaggregative *E. coli* (EAEC) causes acute and persistent diarrhea in children in developing countries, adult traveler's diarrhea, and diarrhea in HIV-infected patients.* The pathogenesis of EAEC infection comprises colonization of the intestinal mucosa in an aggregative, "stacked brick" pattern by means of one of several different aggregative adherence fimbriae (AAF). Some strains of EAEC may then elaborate cytotoxins, including the plasmid-encoded toxin and the enterotoxins EAST1 and ShET1. EAEC virulence factors are under the control of a global regulator, called AggR, in "typical EAEC strains."[204,327] EAEC infections elicit mucosal inflammation. Some infected subjects develop bloody diarrhea as well as a subset who develop chronic persistent diarrhea; persistent illness is particularly important in young children.[44,227,415] EAEC may be an important, unrecognized cause of childhood diarrhea in the United States.[104]
13. Diffusely adherent *E. coli* (DAEC) has been implicated as a cause of diarrhea in several studies, particularly in children older than 12 months of age.[328,414,442] DAEC is defined by the presence of a characteristic, diffuse pattern of adherence to HEp-2 cell monolayers. DAEC strains produce fimbrial adhesins that belong to the Dr family of adhesins.[254,282] DAEC was isolated in 13 percent of diarrhea cases in children younger than 5 years of age in the emergency department at a children's hospital in the United States, where it may be an important, underrecognized cause of childhood diarrhea.[104]

Vibrio cholerae

Cholera is an acute, severe diarrheal disease caused by *Vibrio cholerae* that affects millions of people each year. Without prompt rehydration, death can occur within hours of the onset of symptoms. Cholera affects people of all ages, but children are involved disproportionately. Strains of *Vibrio cholerae* are classified according to somatic or O groups. *V. cholerae* strains are separated further into two main serotypes (Ogawa and Inaba) and two biotypes (classic and El Tor). *V. cholerae* responsible for epidemic cholera belong to serogroups O1 and in recent decades, O139.[93,97,253] It is estimated that *V. cholerae* causes 1 to 4 million cases of diarrhea and more than 100,000 deaths annually.[10,512] During the past several decades, despite advances in water sanitation technology and antibiotic treatment, the seventh cholera pandemic has spread.[512] The cholera burden has grown strikingly during the past 4 years and has spread to countries previously spared by this disease. The current spread has proved especially violent, as illustrated by the recent deadly epidemics in

*References 2, 44, 157, 172, 228, 422.

East Africa and Haiti.[371] Cholera emerged in Haiti in 2010, with more than 400,000 cases and over 6,000 deaths, and continues today.[487] Cholera is rare in the United States. Most clinical isolates of *V. cholerae* O1 in the United States are associated with foreign travel and with ingestion of undercooked seafood,[88,322,332] and many are resistant to antimicrobial agents.[444] Crabs harvested from the U.S. Gulf Coast are a common source of cholera.[78] After Hurricane Katrina in 2005, crabs were the source of illness for certain cases of cholera.[84,88] Most *Vibrio* infections after the hurricane were *V. vulnificus*, *V. parahaemolyticus*, and nontoxigenic *V. cholerae*. *V. cholerae* O75 has caused cholera in the U.S. Gulf Coast states. Since epidemic cholera began in Haiti in 2010, a total of 23 cholera cases caused by toxigenic *Vibrio cholerae* O1 have been confirmed in the United States.[332]

V. cholerae O1 adheres to and multiplies on small intestinal mucosa. Diarrhea occurs after elaboration of several toxins, the most important of which is cholera toxin (CT) composed of one A and five B subunits.[423] The B subunits bind the toxin to the terminal galactose of G_{M1} ganglioside receptors present on intestinal mucosal cells. Inside the epithelial cell, the A subunit activates adenylate cyclase, initiating continuous cyclic adenosine monophosphate production. This results in chloride and fluid secretion into the small intestine lumen.[238,253,423] Strains of *V. cholerae* belonging to serotypes other than O1 and O139 are much less significant pathogens, although they can cause mild and occasionally profuse, watery diarrhea. Other *Vibrio* spp., including *V. fluvialis*, *V. mimicus*, *V. hollisae*, and *V. furnissii*, have been shown occasionally to cause gastrointestinal tract disease.[238]

Vibrio parahaemolyticus

V. parahaemolyticus inhabits warm estuarine waters worldwide. The organism has been found in water, shellfish, fish, and plankton[221] and has caused outbreaks of gastroenteritis after ingestion of contaminated seafood.[305,322] Although widely distributed in coastal waters, *V. parahaemolyticus* is an uncommon cause of diarrhea where consumption of raw seafood is common. Clinical manifestations of infection with *V. parahaemolyticus* are gastroenteritis in 59 percent of cases and include abdominal cramps, nausea, and, less frequently, vomiting, headache, low-grade fever, and chills; wound infections, including hemorrhagic cellulitis in 34 percent; and septicemia in 5 percent.[118] A dysentery-like syndrome has been described in India and Bangladesh.[229] Preexisting liver disease predisposes infected patients to development of septicemia and death.[221] Surveillance data from the United States indicate that the incidence of vibriosis increased from 1996 to 2010 overall and for each of the three most commonly reported species: *V. parahaemolyticus*, *V. vulnificus*, and *V. alginolyticus*.[333]

Yersinia enterocolitica

Yersinia enterocolitica is a gram-negative bacillus that appears to be a common cause of gastroenteritis among children in Europe and Canada but is a relatively uncommon cause of enteritis in the United States.[52] The ingestion of contaminated milk or food such as chitterlings[132,246,283] has been implicated as the mode of transmission in reported outbreaks. The clinical manifestations vary according to the age of the person involved. Illness in children younger than 5 years usually is self-limited gastroenteritis. Stools may contain blood and mucus or be watery. Associated symptoms consist of fever, vomiting, and abdominal pain. Older children may present with abdominal pain associated with mesenteric adenitis that mimics acute appendicitis. Adults develop diarrhea and abdominal pain less frequently than do children but may present with polyarthritis, arthralgia, or erythema nodosum. Patients with β-thalassemia and iron overload are at an increased risk for development of severe yersiniosis.[4]

Aeromonas hydrophila

Aeromonas spp. are gram-negative bacteria found in soil and fresh and brackish water worldwide. *Aeromonas* spp. are recognized as colonizers and pathogens of cold-blooded animals, including fish, reptiles, and amphibians. *Aeromonas* spp. have been associated with a wide spectrum of human disease, most frequently gastroenteritis, soft tissue infection, and bacteremia, especially in immunocompromised hosts.[237] There are many species of *Aeromonas* associated with human diseases; however, *A. hydrophila*, *A. veroni*, and *A. caviae* are the major species associated with gastroenteritis. Because many clinical laboratories cannot perform precise identification, most species isolated are reported as *A. hydrophila*.

The role of *A. hydrophila* in human diarrhea remains controversial. Supporting evidence for aeromonads as intestinal pathogens stems from detailed case reports, epidemiologic case-controlled investigations on *Aeromonas*-associated diarrhea, and generally very low colonization rates in asymptomatic persons.[237] However, one of the impediments to establishing *Aeromonas* as a true gastrointestinal pathogen is the failure to identify a single clonally related outbreak of diarrhea caused by this agent. In addition, volunteers who have been fed the organism have not become ill and no animal model has been established that can faithfully reproduce the diarrheal syndrome.[237] Nevertheless, *Aeromonas*-associated diarrhea occurs worldwide; however, the exact prevalence of this infection on a global scale is unknown.[425] Children with watery diarrhea associated with *Aeromonas* are significantly more likely to have organisms that possess genes for both heat-labile and heat-stable enterotoxins than control children.[6] *Aeromonas* has been linked to cholera-like and dysentery-like illness.[237]

Plesiomonas shigelloides

Plesiomonas shigelloides is a gram-negative bacillus that has been associated with opportunistic infections in immunocompromised hosts and with sporadic cases of diarrhea in immunocompetent hosts in a variety of countries.[145,224,250,257] In some case-control studies, the organism has been found to be associated with diarrhea, whereas in others it has not.[7] The organism has been isolated from surface water and the intestines of

freshwater fish and many animals, including dogs and cats.[462] *Plesiomonas* occurs commonly in tropical and subtropical areas from which most stool isolates have been reported.[224] Patients with *P. shigelloides* infection describe self-limited diarrhea, occasionally characterized by blood and mucus. The organism has failed to produce illness when fed to volunteers, and its role as an enteric pathogen remains uncertain.[213]

Clostridium difficile

Clostridium difficile is the most common bacterial agent associated with severe antimicrobial-associated diarrhea. Enterotoxin A and cytotoxin B account for most of its virulence. The epidemiology of *C. difficile* among children is not well understood. Asymptomatic colonization is very common in neonates and young children; reported rates range from 0 to 50 percent in neonates and up to 70 percent in infants. Frequency of colonization gradually decreases with age: after 4 years of age, rates are less than 5 percent, similar to those of healthy adults.[64] Despite the high frequency of colonization by *C. difficile*, infants rarely develop symptomatic disease. In older children, *C. difficile* disease was traditionally considered a hospital-acquired infection but community-acquired infection has been increasingly described.[90]

Clostridium perfringens

Clostridium perfringens types A, C, and D produce an enterotoxin that is implicated in the pathogenesis of a short-duration food poisoning syndrome.[423] Most foodborne outbreaks are caused by type A strains. Within 14 hours after ingesting contaminated food (meat or poultry products), patients experience watery diarrhea and abdominal pain with minimal nausea, vomiting, or fever; illness resolves in less than 24 hours. *C. perfringens* type C also is associated with a rare destructive intestinal disease called *enteritis necroticans* or *pigbel*, characterized by vomiting, abdominal pain, bloody diarrhea, and small bowel necrosis, with peritonitis, shock, and death.[326,484] These strains produce three toxins (α-toxin, β-toxin, and an enterotoxin) of potential pathogenetic significance.[310,422] Enteritis necroticans occurs after ingestion of undercooked pork.

Staphylococcus aureus

Staphylococcus aureus produces a wide variety of toxins including staphylococcal enterotoxins and staphylococcal-like proteins.[25] Staphylococcal enterotoxins are a major cause of food poisoning, which typically occurs after ingestion of processed meat or dairy products, which have been contaminated with *S. aureus* due to improper handling and subsequent storage at elevated temperatures. Symptoms include nausea and vomiting, with or without diarrhea. The illness is usually self-limiting, and only occasionally is it severe enough to warrant hospitalization.[420] The severity of the illness depends on the amount of food ingested, the amount of toxin in the ingested food, and the general health of the host. Staphylococcal enterotoxin type A has been responsible for more than half of the reported outbreaks of staphylococcal food poisoning in the United States.[223,287]

Bacillus cereus

Bacillus cereus is an aerobic, spore-forming, gram-positive bacillus that is widely distributed environmentally; it causes an emetic or a diarrheal food-associated illness primarily in the industrialized world.[53] *B. cereus* is associated mainly with food poisoning but can also cause potentially fatal nongastrointestinal infections.[53] Although frequently present in food, *B. cereus* should be suspected as the cause of gastrointestinal tract illness if appropriate symptoms are present and if incriminated food, particularly fried rice, contains 10^5 or more *B. cereus* organisms per gram.[72,75]

Two distinct forms of gastrointestinal tract illness can be produced by this organism: the emetic disease, a food intoxication caused by cereulide, a small ring-formed peptide; and a diarrheal syndrome caused by vegetative cells, ingested as viable cells or spores, that produce protein enterotoxins in the small intestine.[446] If the strain causing illness produces the emetic toxin, a syndrome occurs that resembles illness produced by staphylococcal enterotoxin, with nausea, vomiting, and abdominal cramps that begin within 1 to 6 hours of ingestion. If the strain produces enterotoxins, profuse watery diarrhea and abdominal pain begin within 6 to 24 hours, with minimal or no vomiting. Some strains produce both toxins, whereas others produce only one toxin. Symptoms caused by either toxin usually resolve in less than 24 hours and fever rarely occurs. Spores of *B. cereus* are resistant to heat and, therefore, may withstand a brief period of cooking or boiling.

Listeria monocytogenes

Listeria monocytogenes is the causative agent of listeriosis, a potentially fatal opportunistic foodborne infection. *Listeria* spp. are isolated from a diversity of environmental sources, including soil, water, foods, and the feces of humans and animals. The foods most frequently contaminated include soft cheeses and dairy products; pâtés and sausages; smoked fish; and industrially produced, refrigerated, ready-to-eat products that are eaten without cooking or reheating.[32,74,184] *L. monocytogenes* can cause gastroenteritis in otherwise healthy individuals and more severe invasive disease in immunocompromised patients. Common symptoms include fever, watery diarrhea, nausea, headache, cramps, and myalgia.[35,350]

Parasites

The most important parasites known to cause diarrhea are the protozoa (*Entamoeba histolytica*, *Giardia lamblia*, *Cryptosporidium parvum*, *Isospora belli*, *Cyclospora cayetanensis*), and the Microsporidia (*Encephalitozoon intestinalis* and *Enterocytozoon bieneusi*). Among helminths, *Strongyloides stercoralis* and *Trichuris trichiura* may produce diarrhea. Data associating *Ascaris* and hookworm with diarrhea are lacking, but both cause abdominal pain. *Balantidium coli* is a cause of bloody diarrhea in humans. The roles of

Blastocystis hominis[447] and *Dientamoeba fragilis* as causes of diarrhea are controversial.

Entamoeba histolytica

Entamoeba histolytica is the causative agent of amebiasis, a disease that is a major source of morbidity and mortality in the developing world.[387,443] The genus *Entamoeba* contains many species, six of which can reside in the human intestinal lumen. *E. histolytica* is the only species definitely pathogenic. *E. dispar* and *E. moshkovskii* do not appear to be pathogenic. New approaches to identifying *E. histolytica* are based on detection of *E. histolytica*–specific antigen and DNA in stool and other clinical specimens.[160] Clinical patterns that occur in patients with amebiasis consist of intestinal amebiasis, with the gradual onset of colicky abdominal pain and frequent bowel movements, tenesmus, and little or no constitutional disturbance; amebic dysentery, characterized by profuse diarrhea containing blood and mucus and the presence of constitutional signs, such as fever, dehydration, and electrolyte alterations; hepatic amebiasis, which usually presents as abscess formation without gastrointestinal tract symptoms; and asymptomatic colonization.[203] Patients may experience tender hepatomegaly, jaundice, weight loss, fever, and anorexia. The frequency of liver abscess in patients with amebiasis is between 1 and 5 percent. The complications of intestinal amebiasis include perforation, ameboma, stricture, hemorrhage secondary to erosion into a blood vessel, intussusception, ischiorectal abscess, fistulas, and rectal prolapse.[203]

Giardia intestinalis

Giardia intestinalis (synonyms: *G. lamblia* and *G. duodenalis*) is a flagellated protozoan parasite that reproduces in the small intestine, causing giardiasis. *Giardia* is one of the most common intestinal parasites in the world; it contributes to diarrhea and nutritional deficiencies in children in developing regions.[11] In the United States it is the most common intestinal parasite identified by public health laboratories.[81] *Giardia* infection is transmitted by the fecal-oral route and occurs after ingestion of *Giardia* cysts in fecally contaminated food or water or through person-to-person transmission.[142,288,295] The low infectious dose of 10 cysts places people in close contact, including children in daycare, at risk of acquiring infection.[390] Children appear to be more susceptible to *Giardia* than adults. Specific conditions that predispose to giardiasis are hypogammaglobulinemia, secretory immunoglobulin A (IgA) deficiency, peptic ulcer disease, biliary tract disease, and pancreatitis. The parasite may exist in two forms: cyst and trophozoite. The trophozoites usually are seen in duodenal aspirates and loose stools, whereas cysts can be found in formed stools and can remain viable and infectious in water for longer than 3 months. Diagnostic assays using antigen detection are available.[11]

Giardia infection can be asymptomatic or present as an acute illness with a sudden onset of explosive, watery, foul-smelling stools and flatulence, abdominal distention, nausea, and anorexia, with the absence of blood and mucus or as chronic diarrhea and malabsorption, with exacerbations and remissions of flatulence, abdominal distention, and abdominal pain often lasting for months.[372] *Giardia* infections can result in chronic gastrointestinal disorders such as postinfectious irritable bowel syndrome, and symptoms may manifest at extraintestinal sites, even though the parasite does not disseminate beyond the gastrointestinal tract.[112]

Cryptosporidium

Cryptosporidium is an intestinal coccidian protozoan parasite that causes diarrheal diseases in humans worldwide. Children and immunosuppressed individuals, especially those with HIV infection or AIDS, are disproportionately affected.[65] In developing countries there is a high prevalence of cryptosporidiosis in young children, particularly among those who are malnourished or HIV infected.[226,320,352] Fecal-oral transmission of *Cryptosporidium* oocysts occurs from person to person, through ingestion of contaminated drinking water or recreational water, through consumption of contaminated food, or by contact with infected animals (cattle and sheep).[86,88,142,222,288] Unlike bacterial pathogens, *Cryptosporidium* is resistant to chlorine disinfection and can survive for days in treated recreational water, including swimming pools and recreational water parks.[142] Children aged 4 years old and younger appear to be at a particularly high risk for acquiring this organism.[88] *Cryptosporidium* has been implicated as a cause of diarrhea in travelers and of epidemics in hospitals, daycare centers, and other institutional settings worldwide. The largest waterborne outbreak of diarrhea documented in the United States was caused by *Cryptosporidium*. The incubation period in humans has been estimated to be 2 to 14 days.

Cryptosporidiosis can be manifested with a wide spectrum of symptoms, including asymptomatic excretion, acute diarrhea, chronic diarrhea, epidemic diarrhea, severe life-threatening watery diarrhea, and biliary tract disease.[101] Watery diarrhea is the hallmark of symptomatic infections, but few, if any, features distinguish gastroenteritis caused by *Cryptosporidium* in the immunocompetent patient from other enteric infections. Stools do not contain blood or leukocytes. Vomiting, flatulence, abdominal pain, and low-grade fever routinely accompany diarrhea.[207] Symptoms usually subside in an average of 9 days. Patients may have cholera-like illness, transient diarrhea, relapsing episodes, or a protracted clinical course with unremitting, profuse diarrhea lasting for months accompanied by profound malabsorption and weight loss.

In immunocompetent individuals, infection with this parasite may be asymptomatic or cause a self-limiting diarrheal illness. However, in immunocompromised patients such as those with HIV infection or AIDS, *Cryptosporidium* spp. may cause severe, chronic, and possibly fatal diarrhea and wasting. Before HAART was instituted, enteritis caused by *Cryptosporidium* occurred in 10 to 15 percent of patients with AIDS in the United States and approximately 15 percent of patients with AIDS in the developing world.[299] Identification of the organisms and symptoms is more frequent when the CD4 count is less than 200 cells/μL. Antiretroviral therapy is

protective against disease.[69,299] The emergence of drug-resistant HIV variants and failure or discontinuation of HAART has been associated with reemergence of *Cryptosporidium* spp. infection in HIV patients.[338]

Isospora belli

Isospora was established as a cause of diarrhea in humans in the early 1900s, when sporadic cases of isosporiasis and a few clinical series were reported in the medical literature.[130] *I. belli* gained importance with the advent of AIDS and before HAART was shown to be an important cause of severe and prolonged gastroenteritis.[356] Infection can occur in adults and children and has been reported in infants with severe diarrhea.[289] This organism also has been implicated as a cause of traveler's diarrhea.[171] Transmission is fecal-oral, through ingestion of oocysts contaminating food, water, or environmental surfaces.[289] The clinical spectrum of disease caused by *Isospora* is indistinguishable from that described for *Cryptosporidium*. The spectrum includes asymptomatic infection, acute diarrhea in children in developing countries, and chronic diarrhea or severe protracted life-threatening diarrhea in patients with AIDS.[194] Fever, malaise, abdominal pain, and headache have been reported. Stools are watery and do not contain blood or leukocytes. Malabsorption, steatorrhea, severe weight loss, and chronic diarrhea lasting months to years are the most likely occurrences in immunocompromised hosts.[120]

Cyclospora

Cyclospora cayetanensis, a coccidian protozoon, is transmitted by the fecal-oral route. Direct person-to-person transmission is unlikely to occur because excreted oocysts require days to weeks under favorable environmental conditions to sporulate and to become infectious. An animal reservoir has not been described. Outbreaks of diarrhea caused by consumption of water and fresh fruits contaminated with *Cyclospora* have been described,[215,295,297] and travelers to developing countries are at increased risk for development of diarrhea caused by *Cyclospora*. Most of the reported cases have occurred during the spring and summer. The mean incubation period appears to be 7 days.

Clinical manifestations include asymptomatic excretion, acute watery diarrhea, and diarrhea that may be protracted for days to weeks with frequent, watery stools, which may remit and relapse.The clinical presentation is somewhat different in areas of endemicity, where asymptomatic infections are more frequent. Nevertheless, younger children have more severe clinical symptoms. In endemic settings, infections tend to be milder as children get older, because the duration of the infection is shorter and the severity of disease decreases. As in young children, the elderly may also present with a more severe illness.[353]

Microsporidia

Microsporidia have emerged as causes of opportunistic infections associated with diarrhea and wasting in AIDS patients. Among non–HIV-infected but immunesuppressed individuals, microsporidia have infected organ transplant recipients, diabetics, children, the elderly, and patients with malignant disease. In otherwise healthy immune-competent HIV-seronegative populations, self-limiting diarrhea occurred in travelers and as a result of a foodborne outbreak associated with contaminated cucumbers. Greater awareness and implementation of better diagnostic methods are demonstrating that microsporidia contribute to a wide range of clinical syndromes in HIV-infected and non–HIV-infected people.[129]

The nontaxonomic term *human Microsporidia* can refer to any of the order of Microsporidia known to cause disease in humans: *Enterocytozoon* spp., *Encephalitozoon* spp., *Pleistophora* spp., and *Nosema* spp. Of these, *Enterocytozoon bieneusi* and *Encephalitozoon intestinalis* are the most important in gastrointestinal tract disease of humans.[31,486] Both species have been detected in intestinal biopsy specimens of patients with AIDS, with a clinical picture of prolonged diarrhea and weight loss.[111] The clinical spectrum appears to depend on the immune status of the host. The primary location of all intestinal spore-forming protozoal infection is the small intestine, but colonic infection has been reported with *E. bieneusi*.[180] Infection of the biliary tract with *E. bieneusi* and *E. intestinalis* in patients with AIDS can cause sclerosing cholangitis[378,429,493] and acalculous cholecystitis. *E. intestinalis* can infect lamina propria macrophages, fibroblasts, and endothelial cells and can disseminate to other organs, including liver, respiratory tract, and kidney.[180,493] Extraintestinal infection develops after infection with other species of the order of Microsporidia occurs.

Strongyloides stercoralis

Strongyloides stercoralis is a nematode that infects humans through the intestinal tract or through skin if either comes in contact with soil that contains larvae. About one third of people with strongyloidiasis are asymptomatic, and the remainder may have skin, pulmonary, or, more frequently, gastrointestinal tract involvement.[434] People at risk include residents and travelers to endemic areas; natives and residents of the Appalachian region in the United States; institutionalized patients; and people treated with corticosteroids, cimetidine, and antacids.[167] Epigastric abdominal pain occurs and is associated with diarrhea that contains mucus and blood. Some patients may complain of nausea, vomiting, and weight loss with evidence of malabsorption. Eosinophilia and an urticarial rash are prominent features of infection. Diagnosis of *Strongyloides* is often delayed, owing to patients presenting with nonspecific gastrointestinal complaints, a low parasite load, and irregular larval output. Novel diagnostic methods are expected to improve epidemiologic studies and control efforts for prevention and treatment of strongyloidiasis.[317]

The hyperinfection syndrome caused by *Strongyloides stercoralis* has a high mortality rate (15% to 87%). Risk factors include new immunosuppressive therapies, human T-lymphotropic virus (HTLV)-1 infection, cadaveric transplantation, immune reconstitution syndrome, hematologic malignancies (especially lymphoma), tuberculosis,

TABLE 44-7 **Diagnostic Evaluation of the Main Enteropathogens Associated with Pediatric Diarrhea**

Type	Enteropathogen	Laboratory Test
Virus	Rotavirus	Immunoassays: ELISA (preferred method), EIA, immune-chromatography, latex agglutination; reverse transcriptase-PCR (RT-PCR)
	Norovirus	Real time or conventional RT-PCR (preferred method); EIA (less sensitive)
Bacteria	*Shigella*	Conventional stool culture; fecal leukocytes
	Salmonella	Conventional stool culture; blood and bone marrow culture for systemic disease; serotype
	Campylobacter	Stool culture with special media, incubated at 42°C, with microaerophilia; Gram stain; EIA
	Shiga toxin–producing *E. coli*	Simultaneous culture for O157 STEC (sorbitol-MacConkey) and non-culture assay for Shiga toxin detection (ELISA and other enzyme immunoassays) (preferred method); PCR (see Table 44-6)
	Other diarrheagenic *E. coli*	Conventional stool culture for initial isolation of *E. coli* colonies, followed by a specific assay; conventional or real time PCR; HEp-2 cells adherence assays; toxin detection by EIA (see Table 44-6)
	Vibrio cholerae	Stool culture in salt-containing media, with study of isolates for O1 serotype
	Vibrio parahaemolyticus	Stool culture in salt-containing media
	Yersinia enterocolitica	Stool culture in selective media
	Aeromonas hydrophila	Conventional stool culture
	Plesiomonas shigelloides	Conventional stool culture
	Clostridium difficile	Detection of toxins A and B in stools by enzyme immunoassay; cytotoxicity tissue-culture assay; stool culture
Parasites	Intestinal parasites associated with diarrhea	Examination of stools for ova and parasites (*Giardia, E. hystolytica, Strongyloides*), and with special stains for coccidia (*Cryptosporidium, Isospora, Cyclospora*) and Microsporidia; enzyme immunoassays (*E. hystolytica, Giardia, Cryptosporidium*) and PCR for all

malnutrition secondary to chronic *Strongyloides* diarrhea, international travel, and immigration.[301,306]

DIAGNOSIS

Determination of the cause of an episode of infectious diarrhea depends on epidemiologic information, the clinical syndrome, laboratory tests, and knowledge or assessment of an organism for virulence factors. Because virulence properties determine clinical manifestations of disease, an understanding of pathophysiologic mechanisms guides the laboratory evaluation and empirical therapy. The major virulence properties of enteropathogens include adherence, epithelial cell invasion, and production of toxins. Some enteropathogens produce diarrhea by other mechanisms, and enteric pathogens may possess one or several of these virulence properties. Both host and microbiologic factors ultimately determine clinical expression in the individual patient. Not all of the recognized virulence properties of a given species are obvious clinically in a given episode of disease.

The diagnosis of gastroenteritis has traditionally been based on cultures and microscopy. However, this pattern may be changing because acute diarrhea diagnostics are moving away from culture toward rapid nonculture methods. These infections are mainly foodborne and therefore preventable, and it is of paramount importance that public health surveillance for these infections is consistent and reliable.[247] Isolation of cultured organisms is still an invaluable tool for determining sensitivity to antimicrobial agents in clinical settings and for identifying specific strains, virulence factors, or toxins during investigations of outbreaks.[366] However, for some pathogens it can be more important to identify the toxins than the organisms themselves; this is the case, for example, for Shiga toxins of STEC/EHEC or for toxins A and B for *C. difficile*. The use of molecular diagnostics is increasing; improvements include multiplex and quantitative PCR, fluorescence in situ hybridization, and metagenomic analyses.[190,247,351,377] It is likely that many isolation-based methods for serotyping, pulsed-field gel electrophoresis, and antimicrobial drug testing will need to transition to sequence-based techniques to remain epidemiologically useful.[247]

Proper identification of the causative agent of an episode of acute infectious diarrhea will help facilitate initiation of appropriate management. In this section we will discuss the basic concepts for enteropathogen identification by direct microscopic examination, stool cultures, immunologic methods, and molecular methods. Laboratory tests used to detect enteropathogens are listed in Table 44-7.

Macroscopic Stool Examination

A gross examination of the stool specimen should be routine in all patients with diarrhea, even if no laboratory studies are performed. Diarrheal stool that is watery and without mucus or blood usually is caused by an enterotoxin, virus, or protozoan organism, or it may be caused by infection outside the gastrointestinal tract. The color of stools generally conveys little information if the stool does not contain blood. Infectious causes to be considered when stools contain blood or mucus include a cytotoxin-producing bacterium, an enteroinvasive bacterium causing mucosal inflammation, and an enteric parasite associated with blood in stools, such as *E. histolytica*,

B. coli, and *T. trichiura*. When it is present, blood usually is mixed evenly into the stool, except in the case of *E. histolytica* infections, in which blood often is on the surface of the stool, and some STEC infections, in which the stool may be blood streaked. Stools that are particularly foul smelling are consistent with *Salmonella* and other bacteria as well as *Giardia*, *Cryptosporidium*, and *Strongyloides* spp. Stools with little odor suggest an enterotoxin, such as cholera toxin or ETEC, or a viral enteropathogen.

Microscopic Examination

Fecal Leukocytes

Microscopic examination of stool specimens for evidence of fecal leukocytes provides information about the cause of diarrhea and helps determine the anatomic location and presence of mucosal inflammation.[373] Fecal leukocytes are produced in response to bacteria that diffusely invade the colonic mucosa and indicate that the patient has colitis. No inflammatory bacterial enteritis exists in which results of the fecal leukocyte examination are uniformly positive.[218] Thus, results of examination are more helpful when they are positive than when negative. When results are positive, the patient probably has an invasive or cytotoxin-producing organism, such as *Shigella* spp., *Salmonella* spp., *Campylobacter* spp., invasive *E. coli*, STEC, *C. difficile*, or *Y. enterocolitica*, although ulcerative colitis and Crohn disease also are associated with fecal leukocytes.

Diarrheagenic *E. coli* is associated with a mild inflammatory response during symptomatic infection in children.[310] Fecal leukocytes generally are not present in stools from patients with diarrhea secondary to viruses, enterotoxin-producing bacteria, or parasites. The leukocytes seen in cytotoxin-associated and invasive bacterial diarrhea syndromes are polymorphonuclear leukocytes. If the fecal leukocyte examination shows evidence of inflammatory enteritis, further laboratory evaluation is indicated. Fecal lactoferrin and fecal calprotectin are new available markers associated with intestinal inflammation. Fecal lactoferrin is a much more sensitive indicator of inflammatory diarrhea than the fecal leukocyte or occult blood test,[94,230] but it may not be useful in differentiating inflammatory from noninflammatory diarrhea in diarrhea-endemic countries.[30] Fecal calprotectin can also be used to screen for bacterial diarrhea and to differentiate between bacterial and viral pathogens in children with gastroenteritis.[95,451]

Ova and Parasites

Normally, examination of stools for ova and parasites is unnecessary unless the patient has a history of recent travel to high-risk areas, stool cultures are negative for other enteropathogens, the patient is involved in an outbreak of parasitic diarrhea, diarrhea persists for longer than 1 week, or the patient is immunosuppressed. Both trophozoites and cysts of *G. lamblia* and larvae of *Strongyloides* spp. can be identified on direct smears of stool specimens. However, the sensitivity of stool examination for most parasites can be improved by use of a concentration technique and by placement of stools in vials containing a stool preservative. Trichrome and iron hematoxylin both are useful as permanent stains for *Giardia* spp. Pooling of preserved fecal samples is an efficient and economical procedure for detecting ova and parasites.[8] Rational use of the stool ova and parasite examination relies on communication between the clinician and laboratory personnel.[57] For patients in whom giardiasis, cryptosporidiosis, isosporiasis, or strongyloidiasis is considered and in whom stool cultures are negative, aspiration or biopsy of the duodenum or upper jejunum may be indicated. Because these organisms live in the upper intestine, this procedure is more reliable than is examination of stool specimens.[396] *E. histolytica* can be diagnosed by microscopic examination of fresh stool specimens or bowel wall scrapings for cysts or trophozoites. A concentration technique may be helpful in demonstrating amebic cysts. Examination of several stool samples by an experienced technician may be necessary because excretion of cysts often is intermittent and interpretation is difficult. Confusion in differentiating amebic cysts from fecal leukocytes may occur. Microscopy can be used only as presumptive evidence of *E. histolytica* because the nonpathogen *E. dispar* is morphologically identical.[146]

Special Stains for Coccidia

Diagnosis of *Cryptosporidium*, *Isospora*, *Cyclospora*, and the Microsporidia is based on morphologic appearance and staining of stool or histologic examination of tissue sections.[180] Among the most widely used stains to visualize these coccidia are standard acid-fast or modified acid-fast stains, which are based on the use of reagents that enhance the penetration of fuchsin into the organism without the need for heating (modified Kinyoun acid-fast stain). In a modified acid-fast stain, *Cryptosporidium* oocysts, which are 4 to 6 μm with four crescentic sporozoites, stain red and can be differentiated readily from yeasts that stain green.[210] In a study of seven microscopy-based *Cryptosporidium* oocyst detection methods, false-positive results were detected by acid-fast and auramine-rhodamine stains but not by monoclonal antibody–based methods.[27] Oocysts of *I. belli* often are visualized by wet-mount preparations because of their size, which is 20 to 30 μm with four sporozoites in two sporocysts. *Cyclospora* oocysts are 8 to 10 μm in diameter and are nonrefractile spherical organisms containing two sporozoites in two sporocysts that are seen easily on wet mount preparations and are variably acid fast. Microsporidia are difficult to differentiate from bacteria and debris because of the small size of the spores, which measure 1 to 2 μm. For detection, formalin-fixed stool or duodenal fluid can be stained with a calcofluor stain, a modified trichrome stain, or a fluorescent stain.[128,485] Gram, acid-fast, periodic acid–Schiff, and Giemsa stains also have been used to stain the organism.[426] Small bowel biopsy may be more sensitive than is stool examination for establishing the diagnosis of intestinal microsporidiosis.[41] Spores are Gram positive, and parts of the internal structure are positive for acid-fast or periodic acid–Schiff stains.

Stool Cultures

Obtaining of stool cultures cannot be justified in all patients with acute diarrhea.[218] Patients with mild, self-limited illness do not need to have stool specimens cultured. When culture is indicated, the specimen should be inoculated onto culture plate media adequate to isolate *E. coli*, *Shigella*, *Salmonella*, and *Campylobacter*. Fecal specimens can be transported to the laboratory in a non-nutrient holding medium, such as Cary-Blair, when culture cannot be performed immediately. This medium prevents drying or overgrowth of specific organisms. All bloody stool specimens should be evaluated with MacConkey sorbitol medium for *E. coli* O157:H7.[54] Some bacterial enteropathogens require modified laboratory procedures for identification.[218] If these agents are suspected (e.g., *Vibrio* or *Yersinia*), the laboratory should be notified so that appropriate culture methods can be used.

Shigella and *Salmonella* organisms are isolated routinely by clinical microbiology laboratories. *Shigella* species are determined in most clinical laboratories. Speciation is important in salmonellosis because *Shigella* serotype *choleraesuis* and *Shigella* serotype *typhi* cause more severe disease than do other *Salmonella* spp. Serotyping of *Shigella* serotype *enteritidis* usually is not helpful in the individual case, although serotyping is crucial in evaluation of an outbreak. Because so many *Salmonella* serotypes exist, isolation of an unusual serotype can be of use in the investigation of a foodborne epidemic or identification of a potential reptile source of infection. As with *Shigella*, isolation of a species of *Salmonella*, even without demonstration of virulence properties, is considered adequate to make an etiologic diagnosis. Serologic studies are of no value in the individual patient.

Culture of *Campylobacter jejuni* from stools requires special methods and special media. It can be accomplished with media that contain antibiotics or using membrane filters. Inoculated plates should be incubated with microaerophilia at 42 °C and read at 72 hours.

V. cholerae strains can be isolated from stool with use of thiosulfate–citrate–bile salt–sucrose agar, which is the most convenient and frequently used selective medium. This medium is suitable for most enteropathogenic *Vibrio* spp. except *V. hollisae*. Placement of the specimen into an enrichment broth, such as alkaline peptone water with 1 percent sodium chloride (pH 8.5) for 5 hours before placement on thiosulfate–citrate–bile salt–sucrose agar enhances the isolation of vibrios. Serotyping is necessary to classify organisms into those that cause typical epidemic cholera (i.e., O1 and O139 serotypes) and those that cause less severe disease (i.e., non-O1, or nonagglutinating vibrios).[253] *V. parahaemolyticus*, like other vibrios, can be cultured on thiosulfate–citrate–bile salt–sucrose agar. Strains associated with diarrhea are Kanagawa-positive on Wagatsuma agar (i.e., show hemodigestion resembling β-hemolysis), which is a marker for pathogenicity. *V. parahaemolyticus* can be serotyped on the basis of the O and K antigens.[118]

A. hydrophila can be overlooked easily on standard stool cultures. A specialized blood agar has been suggested for isolation.[13] Oxidase testing of organisms that resemble *E. coli* can select organisms as possible *Aeromonas* spp.[13] If oxidase-positive colonies are found, they can be evaluated biochemically to determine species.

C. difficile can be isolated by anaerobic stool culture on agar containing cycloserine, cefoxitin, and fructose. For establishing a definitive diagnosis, demonstration of the presence of cytotoxin in stool specimens and neutralization with antitoxin or by use of enzyme immunoassay or PCR-based assays are necessary.[9,381,404] *C. perfringens* is isolated commonly from feces of well people. Diagnosis of *C. perfringens* food poisoning requires isolation of the organisms from epidemiologically implicated food in a significant quantity (more than 10^5 organisms/g) or demonstration of 10^6 organisms/g of stool from two or more ill people or demonstration of enterotoxin in stools of two or more ill people.[295]

S. aureus may be isolated from food and may not be the cause of illness because not all strains of *Staphylococcus* produce enterotoxin. Conversely, the absence of *S. aureus* from food that has been reheated just before being eaten does not exclude staphylococcal food poisoning because heating may destroy the organism without inactivating the toxin. Confirmation as a cause of foodborne disease requires isolation of the same phage type *S. aureus* from stools or vomitus of two or more ill persons or detection of enterotoxin in epidemiologically implicated food or isolation of 10^5 organisms/g from epidemiologically implicated food, provided the specimen is properly handled.[295] *B. cereus* can be diagnosed by demonstration of greater than 10^5 organisms/g in the incriminated food or isolation of the organism from stool of two or more ill people and not from stool of control patients.[295]

Listeria is cultured on blood agar plates rather than on the usual enteric media.[468] *Y. enterocolitica* can be isolated from routine media, but a differential selective medium, such as cefsulodin–triclosan (Irgasan)–novobiocin agar, is more effective.[52] Cold-enrichment techniques may increase the yield of the organism from contaminated specimens, such as feces. Stool cultures positive for *Y. enterocolitica* only after prolonged cold enrichment may represent environmental strains of low virulence, unrelated to human disease. Biotyping and serotyping for O3, O8, and O9 are helpful in determining the clinical relevance of such isolates.

Immunologic Methods

Detection of antigens, toxins, and/or antibodies of several important enteric pathogens can be performed using commercially available kits such as enzyme-linked immunosorbent assay (ELISA), enzyme immunoassay (EIA), immune-chromatography, latex agglutination kits, and so on. The sensitivity, specificity, and associated positive and negative predictive values of antigen tests for enteric pathogens differ among them and from those of culture. Rapid tests are available for enteric viruses, bacteria, and parasites.

Among viruses, commercially available enzyme immunoassay and latex agglutination kits are available to detect rotavirus antigen in stool specimens. Assay procedures using monoclonal antibodies have improved the sensitivity and specificity to greater than 95 percent.[123,266] Non–group A rotaviruses are not detected by the commercially

available assays. After the Norwalk virus was cloned and sequenced in 1990,[240] two major types of assays for diagnosing human noroviruses were developed. One detects the viral antigens or antibodies against the antigens by recombinant enzyme immunoassays, and the other detects the viral RNA by RT-PCR.[321] Diagnosis of enteric adenovirus can be established by immune electron microscopy of stool specimens, enzyme immunoassay of stool specimens, or propagation in a line of human embryonic kidney cells transformed by adenovirus type 5 (293 cells).[274] Restriction enzyme analysis is the definitive method for classifying individual enteric adenovirus isolates. Commercially available assays for detection of enteric adenovirus are available.[470] Astroviruses grow well in human embryo kidney cells in the presence of trypsin. Electron microscopy, immune electron microscopy, immunofluorescence on cell culture, enzyme immunoassay, and PCR can be used as detection methods.[174]

Several rapid antigen detection tests are available for enteric bacteria, such as *Campylobacter*, *E. coli* O157:H7, STEC (detection of Shiga toxin 1 and 2), ETEC (detection of ST and LT enterotoxins), and *C. difficile* (detection of cytotoxin A and B).[185,248,264,448]

Numerous serologic tests for amebiasis to detect different types and antibodies are available. Serologic test results for amebae almost always are positive in acute amebic dysentery and hepatic amebiasis. *G. lamblia* and *Cryptosporidium* antigens in feces can be detected by use of one of several rapid and sensitive diagnostic tests.[165,267] Enzyme immunoassays[165,256] and fluorescent monoclonal antibody–based assays [164,401] for detection of *Cryptosporidium* antigen in stool specimens are available. For the Microsporidia, nonspecific fluorescence methods or enzyme immunoassay may enhance speed and sensitivity. After preliminary identification by these stains has been achieved, further examination by electron microscopy is needed to classify adequately the Microsporidia into an appropriate genus. Routine histopathologic studies can provide presumptive identification in infected biopsy tissue; diagnostic confirmation requires electron microscopy. Reliable serologic tests are not available.

Molecular Methods

Although molecular diagnostics are still used primarily in research laboratories, they are highly sensitive and specific in detecting infections in small samples and can simultaneously identify multiple pathogens. Multiplex genetic assays are used to detect different toxins, pathogens, and species or genotypes of the same pathogen.[366] All enteric viruses can be detected by PCR; however, the most widely used is the RT-PCR for norovirus.[175] Several molecular techniques have been developed for detection and differentiation of *E. histolytica*, *E. dispar*, and *E. moshkovskii*[160] and for Microsporidia species *E. bieneusi* and *E. intestinalis*.[119,149] Among bacterial agents, there are several multiplex assay systems to detect for combinations of common enteric bacteria such as *Shigella*, *Salmonella*, *Campylobacter*, *Vibrio*, and other foodborne and waterborne pathogens.* However, worldwide, the most widely used are the PCR systems to detect STEC and other diarrheagenic *E. coli*.

STEC, including O157 and non-O157 serotypes, is a significant foodborne pathogen that requires sensitive and discriminatory methods for detection and characterization. In addition to available immunoassays, there are numerous PCR-based methods, conventional or real-time, for the detection of STEC virulence factors and common serotypes.[22,168,169,170,364] Recent technologic advancements have combined the high-throughput performance of the microarray with the specificity and sensitivity of real-time qPCR to make large-scale screening efforts both time and cost effective.[178]

Diarrheagenic *E. coli* were originally serogroup-defined *E. coli* associated with infantile diarrhea, defined also by their characteristic adherence pattern in tissue-cultured cells.[322] Currently, they are identified mainly based on the presence of specific virulence genes for each pathotype.[254] Conventional methods such as colony-based serotyping are not routinely performed outside reference laboratories and as part of outbreaks investigations. Many "classic" serotypes of each pathotype do not harbor the specific virulence genes of that particular pathotype, and, conversely, some genetically defined strains do not belong to the classic serogroups.[68,504] Therefore, O-serogroup identification of diarrheagenic *E. coli*, especially of EPEC, should not be used in clinical laboratories, except as part of outbreak investigations. One exception is STEC; because *E. coli* O157:H7 is the most virulent strain, it should always be sought in clinical laboratories. Other STEC serotypes (e.g., O104:H4) have also caused massive outbreaks of serious disease and should be defined when the epidemiology so dictates. Tissue-cultured cell methods for the identification of specific adherence patterns (e.g., EAEC and tEPEC) are done only in research laboratories; are laborious and time consuming; are not always specific for virulent strains; and are a challenge when the sample produces few colonies, such as a sample from a patient with early-phase gastroenteritis.[234] These traditional methods for differentiating *E. coli* strains have been replaced with more-sensitive PCR methods performed in *E. coli*–isolated colonies or stool samples. Several multiplex PCR-based platforms have been developed (Fig. 44-3) and validated in different countries.*

TREATMENT

In caring for children with diarrhea and dehydration, the major therapeutic considerations include fluid and electrolyte therapy, dietary management, nonspecific therapy with antidiarrheal compounds, and specific therapy with antimicrobial agents to shorten the duration of the illness and eradicate fecal shedding of the organism (Table 44-8). The timely replacement of fluid loss is the single most important intervention to decrease mortality.

Several guidelines for the management of acute gastroenteritis in children have been developed in the United

TABLE 44-8 **Management of Diarrhea in Children**

Key Points	Description
Rehydration	Clinical assessment of hydration status
	Prevention of dehydration: continue breast-feeding and other milk feeds, encourage intake of fluids available at home
	Oral rehydration therapy with oral rehydration salts (ORS) solutions using the current WHO formulation (reduced osmolarity solution) in mild or moderate dehydration
	Intravenous therapy is required only in hypovolemic shock, obtunded mental status, or ileus.
Nutrition	Start refeeding with the usual age-appropriate diet at the earliest opportunity (4-6 hr after onset of rehydration); no need of a special diet
Antibiotics	Most diarrhea cases in pediatrics do not require antibiotics.
	Antibiotics are recommended for dysentery *(Shigella, Salmonella, Campylobacter),* dysenteric amebiasis, cholera, bacteremia or extraintestinal spread of the infection, and in malnourished or immunocompromised children.
	Antibiotics are not recommended in patients with STEC infection.
Additional therapy	Zinc supplementation (10-20 mg/day) for 10 to 14 days in developing countries
Prevention	Rotavirus vaccination in all young infants
	Exclusive breast-feeding for the first 6 months of age
	Safe and clean weaning foods starting at 6 months of age
	Hand washing with soap, improved water quality, and adequate excreta disposal, especially in resource-limited conditions

States[17,263] and elsewhere* as well as practice guidelines for management of infectious diarrhea in adults[192] and recommendations for management of foodborne illnesses.[19,75] Here we highlight the most important aspects of the management of diarrhea in children.

Fluid and Electrolyte Therapy

Patients who develop diarrhea lose fluid and electrolytes through the gastrointestinal tract by several mechanisms: vomiting, loss of fecal fluid caused by the infecting enteropathogen, and fecal water loss in excess of sodium caused by the intraluminal osmotic effect of unabsorbed nutrients.[219] The composition and amount of lost fluid depend on the rate of stool loss and the causative agent. The higher the rate of stool loss, the greater the sodium loss, probably as a result of rapid passage of intestinal contents through the colon, where sodium-potassium exchange occurs. Stools from patients with cholera or ETEC infection contain sodium in a concentration of 80 to 120 mEq/L, whereas stools from patients with virus infection have sodium concentrations of less than 50 mEq/L.[206,263,410] In secretory diarrheal disorders, loss of fluid generally is derived from the small intestine, and colonic reabsorption is overwhelmed. In viral gastroenteritis, small bowel absorptive capacity primarily is impaired; and in dysenteric or invasive diarrhea, reabsorptive capacity of the large intestine is reduced. If

*References 45, 188, 196, 197, 205, 329, 497.

vomiting also is a manifestation, this loss is compounded. Continued loss of fluid or electrolytes may lead to dehydration, with potentially severe sequelae. Children, especially infants, are more susceptible to dehydration because they have greater basal fluid and electrolyte requirements per kilogram and because they depend on others to meet these needs.

Important factors to be considered in evaluating patients with diarrhea and possible dehydration include an estimation of deficiency, ongoing daily requirements, continued losses and their replacement, and correction of the underlying cause.[17,189,219] The clinical signs and symptoms that may help in estimating deficiencies and determining the severity of dehydration include thirst, dryness of the mucous membranes, decrease in urinary output, tachycardia, loss of skin elasticity and turgor, and mottling and coolness of the skin.[17,79] Various scores have been proposed for the assessment of dehydration and disease severity, but they have not been validated for the assessment of dehydration in individual patients.[188] These signs may be misleading in patients who are malnourished or in patients with hypertonic dehydration.[498,499] In clinical practice, a physical examination enables the clinician to classify patients into the three groups of none, mild/moderate, or severe dehydration. This general assessment can then be used to guide clinical management.

The main complication associated with gastroenteritis is dehydration; it should be prevented with appropriate fluid management. In children with gastroenteritis but without clinical dehydration, it is recommended as primary prevention of dehydration to continue breastfeeding and other milk feeds, encourage intake of fluids available at home, offer oral rehydration salt (ORS) solution as supplemental fluid to those at increased risk of dehydration, and discourage the drinking of fruit juices and carbonated drinks, especially in those at increased risk of dehydration. All these juices and drinks contain inadequate amounts of sodium and potassium and excessive carbohydrate concentrations, which may exceed the absorptive capacity of the intestine and may exacerbate diarrhea due to high osmotic activity.[262,428] The homemade sugar and salt solutions are not recommended because errors in preparing the solutions may result in dangerously high or low sodium concentrations.[424,491]

Oral rehydration should be used as first-line therapy for the management of mild-to-moderate dehydration in children with gastroenteritis. Oral therapy consists of rehydration with replacement of ongoing losses during the first 4 to 8 hours of therapy with a glucose-electrolyte solution.[98,263,410] Children with moderate dehydration should receive ORS ad libitum, approximately 75 mL/kg in 4 or 6 hours, following "Plan B" of the WHO recommendations.[497] When oral rehydration is not feasible, enteral rehydration by the nasogastric route is as effective if not better than intravenous rehydration. Enteral rehydration is associated with significantly fewer major adverse events and a shorter hospital stay compared with intravenous therapy and is successful in most children.[158,208] Once the patient is rehydrated, feeding should be restarted.

The ORS solution must contain glucose, sodium, and other electrolytes that are lost in diarrhea (Table 44-9). The glucose in the ORS solution is necessary to promote intestinal absorption of sodium and water in the small intestine. The formulation ORS solution must preserve the 1:1 molar ratio of sodium to glucose that is critical for efficient cotransport of sodium and glucose. The composition of the original WHO ORS solution was selected to allow for use of a single solution that would effectively treat dehydration secondary to diarrhea caused by various infectious agents and resulting in varying degrees of electrolyte loss, such as cholera or ETEC infection.[263] However, viral gastroenteritis is common in

TABLE 44-9 **Compositions of Rehydration Solutions and Chemical Composition of Diarrheal Stools in Children**

	Osmolarity (mOsm/L)	Glucose (mmol/L)	Sodium (mmol/L)	Chloride (mmol/L)	Potassium (mmol/L)	Citrate (mmol/L)	Bicarbonate (mol/L)
Oral Rehydration Solutions							
Original or standard WHO solution	311	111	90	80	20	10	—
New WHO reduced osmolarity solution	245	75	75	65	20	10	—
Hypotonic osmolarity solution*	240	90	60	60	20	10	—
ReSoMal†	300	125	45	70	40	7	—
Intravenous Fluids							
Ringer's lactate‡	272	—	130	111	4	—	28
Cholera saline (Dhaka solution)§	432	140	133	98	13	—	48
Normal saline	300	—	154	154	—	—	—
Losses in Children							
Cholera stool		—	105	30	25	—	30
Noncholeraic stool		—	52	14	25	—	14

*This is one example; there are several other commercially available ORS solutions with different sodium (50 and 45 mmol/L) and glucose concentrations.
†ReSoMal is a modified oral rehydration solution for patients with severe malnutrition.
‡Preferred IV therapy by WHO recommendations. The base is lactate, not bicarbonate.
§Some preparations do not have glucose and therefore have a lower osmolarity.[294]

pediatric patients and is associated with less severe salt losses, so there was concern that the sodium content of the original WHO ORS solution might be excessive.[133] The current WHO ORS formulation, so-called reduced osmolarity solution, adopted in 2002 (see Table 44-9) has a reduced osmolar load (245 mOsm/L) compared with the original formulation (311 mOsm/L). The so-called hypotonic osmolarity solution, containing sodium 60 mmol/L, is also accepted. Both solutions have reduced the need for unscheduled intravenous fluid infusion and have less stool output and less risk of vomiting compared with the original formulation.[98,201] The rice-based ORS that contains glucose polymers and amino acids may be more beneficial than the glucose-based oral rehydration solution in children with cholera diarrhea.[183] Unlike reduced osmolarity ORS, rice-based ORS does not reduce the need for intravenous infusion.[159]

Intravenous therapy is required if the patient is in hypovolemic shock, has an obtunded mental status, or has an ileus. Children with severe dehydration should receive intravenous fluids immediately. If the patient can drink, ORS should be given by mouth until the drip is set up. Children should receive 100 mL/kg lactated Ringer solution divided as follows: infants (<12 months) 30 mL/kg in 1 hour, followed by 70 mL/kg in 5 hours; older children (>12 months) 30 mL/kg in 30 minutes, followed by 70 mL/kg in 2½ hours, following "Plan C" of the WHO recommendations.[497] If the child is able to tolerate orally administered fluids, intravenous infusion should be stopped and further rehydration completed with oral rehydration therapy alone.[98]

Nutritional Management

Adequate feeding is important to reduce the nutritional defects caused by diarrhea.[17,263] Children with diarrhea who are not dehydrated should be fed age-appropriate diets.[480] Children who require rehydration should be started on refeeding with the usual diet at the earliest opportunity, while the oral glucose-electrolyte solution is continued to replace ongoing losses from stools. It is recommended to feed starting 4 to 6 hours after the onset of rehydration. Early feeding may reduce duration of diarrhea and improve weight gain.[61,188,220]

Breast-feeding in infants should be continued at any time during an episode of diarrhea. Continuing breast-feeding during acute gastroenteritis has been shown to exert a beneficial effect by reducing the number and volume of diarrheal stools and reducing the duration of diarrhea in rotavirus gastroenteritis.[199,259] Refeeding with undiluted or full-strength nonhuman milk (cow's or formula milk) should continue. Weaned children should be fed whatever they eat normally. Full feeding of appropriate-for-age foods is well tolerated and is better than the practice of withholding food, resulting in better weight gain, without increasing complication rates of treatment failures.[406] Controlled clinical trials suggest that complex carbohydrates (rice, wheat, potatoes, bread, and cereals), lean meats, yogurt, fruits, and vegetables are well tolerated in children with mild to moderate diarrhea and should be continued unrestricted as age-appropriate foods after the period of rehydration.[188]

Transient lactose intolerance occurs in some children with gastroenteritis. However, routine use of lactose-free formula is not necessary and only should be indicated in patients with severe and prolonged diarrhea. There is not enough evidence to support the routine use of soy-based formula or hydrolyzate formula in infants with acute gastroenteritis.[26,107] Beverages such as tea, soft drinks, and fruit juices that contain a high sugar concentration should be avoided, owing to the risk of inducing further fluid losses as a consequence of increased osmotic loads.[392,469]

Antimicrobial Therapy

Because viruses are the predominant cause of acute diarrhea in children in developed and developing countries, the routine use of antimicrobial agents for treating diarrhea wastes resources and might lead to increased antimicrobial resistance. Even when a bacterial cause is suspected in an outpatient setting, antimicrobial therapy is not usually indicated in children because the majority of cases of acute diarrhea are self-limited and not shortened by administration of antimicrobial agents. Exceptions to these rules involve special needs of individual children (e.g., immune-compromised hosts, premature infants, or children with underlying disorders) and particular organisms and conditions.[263]

Therapy with antimicrobial agents is important in most cases of diarrhea caused by invasive or inflammatory bacterial pathogens and can be useful in other noninvasive forms of bacterial diarrhea. Recommendations for antibiotic therapy in each form of bacterial diarrhea are provided in Table 44-10. Antibiotics should be used for the treatment of children with suspected or confirmed septicemia; for those with extraintestinal spread of bacterial infection; for children younger than 6 months of age with *Salmonella* gastroenteritis; for those who are malnourished or immunocompromised with *Salmonella* gastroenteritis; and for those with *C. difficile*–associated pseudomembranous enterocolitis, giardiasis, dysenteric shigellosis, dysenteric amebiasis, or cholera.[329]

When antimicrobial therapy is administered to selected patients with gastroenteritis, the aim of the therapy is to abbreviate the duration of the clinical course and to decrease excretion of the causative organisms. A stool culture specimen should be obtained when antibiotic treatment is anticipated, and antibiotic susceptibility testing of any suspected pathogen should be performed to ensure optimal therapy. Changing susceptibility patterns renders the initial selection of an antimicrobial agent difficult. Antimicrobial agents should not be used routinely for gastroenteritis of unknown cause.

Therapy for Dysentery

Dysentery is defined as acute bloody diarrhea typically with abdominal pain and fever caused by invasive microbial infection. The child with bloody diarrhea is at higher risk for complications, including sepsis and other systemic diseases; therefore, the threshold for admission of such children to the hospital for close observation is lower. Stool cultures are indicated in the setting of acute

TABLE 44-10 **Antimicrobial Therapy for Children with Bacterial Diarrhea**

Pathogen	Antibiotic*	Comments
Shigella	Ciprofloxacin	First-line therapy by WHO recommendations; increasing resistance rates in some countries
	Azithromycin, ceftriaxone, pivmecillinam	Second-line therapy by WHO recommendations
	Cefixime, nalidixic acid, furazolidone	Alternative drugs for nonsevere dysentery
	TMP-SMX; ampicillin	High frequency of resistance; use only for susceptible strains
Salmonella	None	For nontyphoidal *Salmonella* diarrhea, except in special patients
	Ciprofloxacin; azithromycin, ceftriaxone	For severe diarrhea in special patients†; or for systemic infection or typhoid fever
	TMP-SMX; chloramphenicol	High frequency of resistance; use only for susceptible strains
Campylobacter	Azithromycin; erythromycin	First-line therapy. High frequency of ciprofloxacin resistance in many countries
STEC	None	May increase the risk of hemolytic-uremic syndrome
ETEC, EAEC, EPEC	Ciprofloxacin; azithromycin; ceftriaxone	Based on recommendations from adults with traveler's diarrhea
	TMP-SMX	High frequency of resistance; use only for susceptible strains
EIEC	Treat as shigellosis	
Vibrio cholerae	Azithromycin, erythromycin	Azithromycin resistance is rare; it is the preferred therapy
	Ciprofloxacin, doxycycline, tetracycline	Alternative drugs; potential toxicity of tetracyclines, use in children >8 year
Diarrhea due to noncholeraic vibrios	None or treat as *Shigella*	
Aeromonas, Plesiomonas	Treat as shigellosis	
Clostridium difficile	Metronidazole, vancomycin	Stop offending antibiotic, if possible

TMP-SMX, trimethoprim-sulfamethoxazole.
*Ceftriaxone is administered intravenously or intramuscularly; all other listed drugs are given orally.
†Infants <6 months of age, malnourished and immunocompromised children.

bloody diarrhea and are helpful for guiding therapy.[370] The four major causes of bloody diarrhea (including both dysenteric and nondysenteric forms) in the United States, in descending order of frequency of occurrence, are *Shigella*, *Campylobacter*, nontyphoid *Salmonella*, and Shiga toxin–producing *E. coli* (STEC).[137] Other organisms may also cause dysentery, including *Aeromonas* species, noncholeraic vibrios, and *Yersinia enterocolitica*. Once laboratory diagnosis is made, pathogen-specific antimicrobial therapy should be initiated for all forms of infectious colitis (*Shigella*, *Salmonella*, and *Campylobacter*) other than STEC.[138] Treatment of dysentery in cases in which stool culture is not available should be targeted at *Shigella*.

Shigella

Mild symptoms are self-limited, but in more severe cases antibiotics are recommended for cure and for preventing complications and relapse. The progressive development of antibiotic resistance in *Shigella* isolates is not new. Ampicillin and trimethoprim-sulfamethoxazole, once affordable mainstays of therapy, have long ago lost efficacy in most *Shigella* endemic regions. Resistance to nalidixic acid, fluoroquinolones, ceftriaxone, and azithromycin and multidrug–resistant strains are also being reported in many countries.[29,270,271] Therefore, regularly updated local or regional antibiotic sensitivity patterns to different species and strains of *Shigella* are required to guide empirical therapy.[100, 270] In the absence of local data, the recommendations from the WHO should be followed. First-line therapy is ciprofloxacin (in all age groups, including pediatrics), and second-line therapy is pivmecillinam (where available), ceftriaxone, or azithromycin.[496] Azithromycin has the added advantage of also treating most isolates of *Campylobacter*, a second major cause of dysenteric diarrhea in children younger than the age of 2 years in developing countries.[271] The antibiotics recommended by the WHO are effective in reducing the clinical and bacteriologic signs and symptoms of dysentery and thus can be expected to decrease diarrhea mortality attributable to dysentery.[465]

Campylobacter

Isolation of *Campylobacter* from stool does not imply the need for antimicrobial therapy. In a meta-analysis of eight randomized, controlled trials of antimicrobial therapy versus placebo, antimicrobial therapy shortened the duration of intestinal symptoms by 1.3 days.[459] The decision concerning therapy should be individualized, but therapy should be considered in patients with high temperatures, bloody diarrhea, severe diarrhea, and in immunocompromised hosts. *Campylobacter* is increasingly resistant to antibiotics, especially fluoroquinolones and macrolides, which are the most frequently used antimicrobial agents for the treatment of campylobacteriosis.[294] Either erythromycin or azithromycin is preferred. In addition to resistance, antibiotic management has also become more complex because postinfectious irritable

bowel syndrome has been associated with a longer duration of untreated infection.[264]

Salmonella

The type of syndrome produced by *Salmonella* (acute gastroenteritis; bacteremia and enteric fever; dissemination with localized suppuration [e.g., abscess, osteomyelitis, or meningitis] influences the selection and duration of antimicrobial therapy. Antibiotics should not be used in the treatment of patients who are nontyphoid *Salmonella* carriers or in most patients with mild gastroenteritis. Antimicrobial therapy may, on occasion, convert intestinal carriage into systemic disease with bacteremia,[397] prolong excretion of *Salmonella*,[28] produce a bacteriologic or symptomatic relapse,[28] or encourage development or selection of resistant strains.

Acute diarrheal disease caused by nontyphoid salmonellosis can be complicated with bacteremia in approximately 8 percent of normal healthy persons. Patients with bacteremia often present with high fever and systemic toxic effects. Risk factors in the host that are associated with a higher than 8 percent risk of systemic *Salmonella* infection during bouts of gastroenteritis include extremes of age (<3 months and ≥65 years), corticosteroid use, inflammatory bowel disease, immunosuppression, hemoglobinopathy including most cases of sickle cell disease, and hemodialysis. People with one of these risk factors and nontyphoid salmonellosis should be treated with antibacterial drugs.[137] Antibiotic treatment of *Salmonella* infection should be given to all patients with typhoid fever, bacteremia caused by nontyphoidal strains, and dissemination with localized suppuration.

Increasing occurrence of antimicrobial resistance in both typhoidal and nontyphoidal *Salmonella* infection is a major public health problem. Recent studies have documented the occurrence of resistance, with particular reference to quinolones and extended-spectrum cephalosporins. Occurrence of multidrug resistance has declined in some areas, but the incidence of decreased ciprofloxacin susceptibility has reached high levels, particularly in the Indian subcontinent, and isolates with full resistance to this antimicrobial agent are increasingly reported. Patterns of resistance in *Salmonella* are constantly changing. Continual surveillance of resistance levels is critical for clinicians to keep abreast of treatment options, but it is often lacking in resource-poor regions of the world with the highest disease burden.[359,406]

Several outbreaks of multiresistant *Salmonella* infection in the United States have been traced to animals.* Resistant strains of *Salmonella* are common findings in retail ground meats, possibly because of overuse of antibiotics in animals used for food.[489] Human isolates of *Salmonella* should have susceptibility testing performed to guide therapy. Recommended antimicrobial agents include chloramphenicol, third-generation cephalosporins, fluoroquinolone, and azithromycin. In the presence of multidrug resistance, a fluoroquinolone is the first line of therapy and a third-generation cephalosporin is the second choice.[406]

*References 71, 166, 176, 252, 421, 450.

Shiga Toxin–Producing E. coli (STEC)

Some antibacterial drugs, including fluoroquinolones and trimethoprim-sulfamethoxazole, may increase the induction of phage-mediated production of Shiga toxin and may increase the risk of development of hemolytic-uremic syndrome.[509] However, an association between the use of these antibiotics and an increased risk of this syndrome has not been proven.[42,402,495] In one study in the United States, individuals with STEC O157 infection presenting with a more severe illness were at an increased risk of developing hemolytic-uremic syndrome; the use of bactericidal antibiotics to treat STEC O157 infection, particularly β-lactams, was associated with the subsequent development of hemolytic-uremic syndrome.[436] In a large prospective surveillance study in Argentina the main risk factor for progression to hemolytic-uremic syndrome was neutrophilic leukocytosis in the early course of the diarrheal episode in STEC-positive children with bloody diarrhea.[292] On the other hand, other drugs, including fosfomycin, azithromycin, and rifaximin, do not appear to increase production of Shiga toxin.[233,235,340] In a mouse model, azithromycin inhibited a Shiga toxin–induced inflammatory response and prevented death.[346] During the STEC O104:H4 outbreak in Germany in 2011, STEC-infected patients were monitored and observed for approximately 40 days; treatment with azithromycin was associated with a lower frequency of long-term STEC O104:H4 carriage.[337] Additional studies are needed to determine the effects of azithromycin and rifaximin on reducing diarrhea and decreasing the risk of the hemolytic-uremic syndrome among patients with STEC colitis. Pending such data, most authorities recommend supportive treatment only; antibiotic therapy is not generally recommended.[137,456] Currently, there is no cure for STEC infection; however, chimeric or humanized monoclonal antibodies have been developed that neutralize the Shiga toxins, and those therapies may be able to prevent the development of hemolytic-uremic syndrome in a STEC-infected patient.[307]

Therapy for Other Bacterial Agents

Diarrheagenic E. coli

Antibiotics are not used routinely for treatment of diarrheagenic *E. coli*, except in traveler's diarrhea. There are no clinical trials on the efficacy of antibiotics for the treatment of the different *E. coli* pathotypes in children, because simple and rapid diagnostic methods are lacking in order to conduct proper trials. Most of the current information on therapy for diarrheagenic *E. coli* comes from case series in children or data from studies in adults. Antimicrobial agents have been employed frequently in attempts to treat infantile gastroenteritis caused by EPEC and as a means of controlling the spread of EPEC strains in hospital nurseries. Although no definitive studies support the effectiveness of these drugs, they may be useful in certain situations, particularly when life-threatening infection occurs or when epidemic spread of the strains continues, despite the use of strict hand washing and appropriate isolation. The treatment in

patients with diarrhea caused by EIEC is similar to that in patients with shigellosis. Diarrhea caused by ETEC and EAEC usually is self-limited, but studies in adults have shown that antimicrobial agents such as ciprofloxacin, azithromycin, and rifaximin are effective therapies.[358] Antimicrobial resistance in diarrheagenic *E. coli* is an increasing problem worldwide[16,335,344,347] as well as the resistance of commensal *E. coli*.[39,141] Therefore, regional antibiotic sensitivity patterns to different *E. coli* pathotypes are required to guide empirical therapy when a decision is made to treat an individual patient.

Cholera

Effective antibiotic treatment reduces the volume and duration of diarrhea in patients with cholera and reduces the number of days that symptomatic patients shed viable *V. cholerae*. Tetracyclines, quinolones, and macrolides are active against *V. cholerae*; however, antibiotic resistance occurs frequently, and resistant strains can emerge rapidly. Therefore, the choice of antibiotic agent is based on results of local antibiotic resistance patterns. Stool cultures performed as part of a surveillance program are also useful for monitoring trends in antimicrobial resistance. In areas of endemicity, many strains have become resistant to tetracycline and to fluoroquinolones. In these areas, azithromycin treatment is preferred and is administered as a single dose of 1 g in adults and 20 mg/kg in children. At present, azithromycin resistance remains rare; and owing to the potential toxicity of tetracyclines and fluoroquinolones in children and pregnant women, azithromycin is also preferred for these patients.[258,487]

Therapy for Intestinal Parasites

Entamoeba histolytica

Metronidazole is the most commonly used medication for invasive amebiasis caused by infection with *Entamoeba histolytica*. The efficacy of available treatments was assessed in a meta-analysis: tinidazole was better than metronidazole at reducing clinical failure and was better tolerated; combination drug therapy was more effective in reducing parasitologic failure compared with metronidazole alone.[179]

Giardia

Metronidazole, tinidazole, secnidazole, and ornidazole are effective therapies for *Giardia*.[501] Occasionally, the initial improvement is followed by a subsequent relapse of symptoms, which requires repeat treatment. Some patients experiencing relapse needed combination therapy. A recent meta-analysis has shown that albendazole, given as a single dose of 400 mg/day for 5 days, was comparable to metronidazole, with fewer side effects.[439] There are new antigiardial drugs being developed.[458]

Cryptosporidium

Children and immunosuppressed individuals, especially with HIV infection or AIDS, are disproportionately affected. Nitazoxanide given to HIV-negative Zambian children with diarrhea eradicated infection, stopped diarrhea, and reduced mortality, whereas no benefit was seen in children who were HIV positive.[15] Recent research confirms the limited effectiveness of antiparasitic drugs to treat cryptosporidiosis in AIDS.[65] Questions remain about using partially active drugs paromomycin and nitazoxanide for treatment. Potent antiretroviral combinations modify disease epidemiology and are key components of therapy in AIDS. However, it is unclear whether this is due solely to immune reconstitution or due in part to antiparasitic effects of HIV protease inhibitors.[65]

Cyclospora

The treatment of choice for infection with *Cyclospora* is trimethoprim-sulfamethoxazole. Ciprofloxacin or nitazoxanide can be used as an alternative therapy, especially in patients who are allergic to sulfa products.[353]

Microsporidia

For microsporidial infections other than with *Enterocytozoon bieneusi*, albendazole is effective. A randomized trial showed that albendazole therapy was effective in improving the clinical manifestations and decreasing the duration of the illness of children with diarrhea caused by the Microsporidia.[466] *Encephalitozoon intestinalis* is susceptible to albendazole,[106,394] which has been reported to stop diarrhea and weight loss as well as to promote weight gain in patients infected with *E. intestinalis*,[315,466] although improvement has not been uniform. *E. bieneusi* does not respond to albendazole but does respond to fumagillin, which is more toxic.[316] For all patients with HIV/AIDS antiretroviral treatment to raise the CD4 count is a major element in management.[501]

Strongyloides

Patients infected with *S. stercoralis* should be treated with ivermectin or, alternatively, thiabendazole or albendazole. In disseminated strongyloidiasis, ivermectin or thiabendazole therapy should be continued for at least 5 days. In immunocompromised patients and patients with *Strongyloides* hyperinfection, longer duration of therapy may be necessary[286]; however, the mortality rate is high despite therapy. In hyperinfection syndrome, rapid initiation of therapy with broad-spectrum antibiotics and anthelminthic drugs is the first step in management. A thorough examination should be performed before immunosuppressive therapy is given to a patient with a history of infection with *S. stercoralis*.[301]

Additional Therapy

Zinc

Zinc is an important trace element in gastrointestinal structure and function. It is involved in epithelial barrier integrity, tissue repair, and immune function.[43,382,427] Zinc deficiency, which is common in young children in developing countries, is worse because intestinal losses of zinc

are considerably increased during acute diarrhea.[70,275] Several studies and meta-analysis have shown that zinc supplementation can reduce the incidence of respiratory and diarrheal diseases.[46,60,399] In developing countries, zinc supplementation results in clinically important reduction in the duration and severity of acute diarrhea when given as an adjunct to oral rehydration therapy.[33,368,398,412] The WHO recommends zinc supplementation to all children with diarrhea in a dosage of 10 mg/day in those younger than 6 months of age and 20 mg/day in older infants and children for 10 to 14 days.[499,500] Zinc decreases the severity and reduces the number of episodes of diarrhea occurring within 2 to 3 months after the intake of zinc. Recent meta-analyses have shown that in areas where the prevalence of zinc deficiency or the prevalence of moderate malnutrition is high, zinc supplementation in children is associated with a reduction in the morbidity and mortality of diarrhea,[479,503] especially among children older than 6 months of age.[281] However, the role of zinc supplements in developed countries needs further evaluation.[113,275]

Probiotics

Probiotics are living nonpathogenic microorganisms that have been studied for prevention and treatment of a variety of disorders, including diarrhea, irritable bowel syndrome, and inflammatory bowel disease.[14,461] The most commonly used strains are lactic acid bacteria, such as lactobacilli or bifidobacteria, and the nonpathogenic yeast *Saccharomyces boulardii.* The rationale for the use of probiotics to treat and prevent diarrheal diseases is based on the assumption that they modify the composition of the colonic microflora and act against enteric pathogens. However, the exact mechanism by which probiotics exert their activity against enteropathogens in humans remains unknown. The possible mechanisms of action include competition with pathogens for binding sites and substrates, lowering of intestinal luminal pH, production of bacteriocins, promotion of mucin production, upregulation of genes mediating immunity, and production of trophic short-chain fatty acids to promote mucosal cell growth and differentiation.[236] Several meta-analyses have shown moderate clinical benefit of selected probiotic strains in treatment of acute watery diarrhea (primarily rotaviral) mainly in infants and young children.[403,413,451,452] *Lactobacillus* GG and *Saccharomyces boulardii* were found to be beneficial in meta-analyses devoted to single probiotics. The beneficial effects of probiotics in acute diarrhea in children seem to be moderate, strain-dependent, dose-dependent (greater for doses $>10^{10}$ to 10^{11} colony-forming units), significant for watery diarrhea and viral gastroenteritis but not for invasive bacterial diarrhea, more evident when treatment with probiotics is initiated early in the course of disease, and more evident in children in developed countries.[188] A recent meta-analysis suggests a protective effect of probiotics in preventing antibiotic-associated diarrhea in pediatric patients.[245]

Antisecretory Agents

Racecadotril (also known as acetorphan) is an antisecretory drug that exerts its antidiarrheal effects by inhibiting intestinal enkephalinase, thereby preventing breakdown of endogenous enkephalins in the gastrointestinal tract and reducing secretion of water and electrolytes into the gut.[383] Racecadotril as an adjunct to oral rehydration therapy has been shown to decrease 48-hour stool output, median duration of diarrhea, and intake of oral rehydration solution in children with severe watery diarrhea. Racecadotril should be considered in the treatment of gastroenteritis in children.[188,196] A recent individual patient data meta-analysis showed that racecadotril has an effect on reducing diarrhea (duration, stool output, and stool number), irrespective of baseline conditions (dehydration, rotavirus, or age) and treatment conditions (inpatient or outpatient studies).[285]

Bismuth subsalicylate and other bismuth salts preparations are used to control diarrhea and other gastrointestinal symptoms. Although the precise mechanism of their action remains unknown, their effect is thought to be due to intestinal antisecretory[144] and antimicrobial properties.[300] Laboratory studies showed that bismuth subsalicylate inhibited intestinal secretion caused by *E. coli* and cholera enterotoxins, reduced diarrhea in adult students who became ill in Mexico,[140] and prevented diarrhea among U.S. students traveling to Mexico.[139] Studies supporting its use in children are limited.[440,441] Three randomized controlled trials that compared bismuth subsalicylate with placebo in infants with acute watery diarrhea found that bismuth subsalicylate only modestly reduced the duration and severity of diarrhea.[99,151,441] In addition to temporary side effects (i.e., darkening of the tongue and stool), bismuth subsalicylate has been reported to cause salicylate toxicity in children.[375]

Loperamide is an opioid receptor agonist that reduces intestinal lumen motility. It is used for short-term symptomatic relief of acute diarrhea in adults; however, it should not be used in the management of diarrhea in children.[188]

PREVENTION

Despite the continued reduction in overall disease burden with increased public health measures, such as improved sanitation, use of antimicrobial agents, and greater public awareness, enteric infections continue to cause significant morbidity and mortality in vulnerable populations. New methods for prevention, management, and treatment of diarrhea, including an improved oral rehydration formulation, zinc supplementation, and rotavirus vaccines, make now the time to revitalize efforts to reduce diarrhea mortality worldwide.[409] In addition to these important preventive measures and the development of new enteric vaccines, breast-feeding, safe weaning foods, water quality, hygiene, and sanitation are critical for prevention of diarrhea in children, especially in developing countries, where the disease burden is higher.

Breast-feeding is the most cost-effective intervention for protecting children against diarrhea and all causes of mortality.[246] Lack of exclusive breast-feeding among neonates from birth to 5 months of age and no breast-feeding among infants 6 to 23 months of age are associated with increased morbidity and mortality from diarrhea in developing countries. There is a large body of evidence

regarding the protective effects of breast-feeding against diarrhea incidence, prevalence, hospitalizations, diarrhea mortality, and all-cause mortality. These findings support the current WHO recommendation for exclusive breast-feeding during the first 6 months of life as a key child survival intervention and also highlight the importance of breast-feeding to protect against diarrhea-specific morbidity and mortality throughout the first 2 years of life.[279]

Contaminated foods, especially in the weaning groups, play a major role in the occurrence of diarrheal diseases. The frequency of contamination of weaning foods with enteropathogens is high in developing countries and is dependent on the food type, storage time, and ambient temperature of storage, the method used, and the temperature reached on rewarming before refeeding. Other considerations are the bacterial content of cooking and feeding utensils. Fruit and raw vegetables can become contaminated with pathogenic microorganisms by sewage-containing irrigation water and by washing produce and fruits with contaminated water. In most studies, the level of contamination is higher in weaning foods than in drinking water.[280] Food safety education is a critical and essential element in control and prevention of diarrheal diseases.[430]

The effect of water quality, hygiene, and sanitation in preventing diarrhea deaths has always been debated. In a recent systematic review, diarrhea risk reduction was estimated to be 48% with hand washing with soap, 17% with improved water quality, and 36% with excreta disposal. Most of the evidence is of poor quality, and more trials are needed; nevertheless, the evidence is strong enough to support the provision of water supply, sanitation, and hygiene for all.[66] A growing understanding of what drives hygiene behavior and creative partnerships are providing new approaches to change behavior.[116]

Vaccines

Enteric infections are a major cause of morbidity and mortality in developing countries. To date, vaccines have played a limited role in public health efforts to control enteric infections. Licensed vaccines exist for cholera and typhoid, but these vaccines are used primarily for travelers. There are two internationally licensed vaccines for rotavirus, but they are mainly used in affluent countries. The reasons that enteric vaccines are little used in developing countries are multiple and certainly include financial and political constraints.[103] In populations in industrialized countries, live attenuated vaccines (e.g., poliovirus, typhoid, and rotavirus) mimic natural infection and generate robust protective immune responses. In contrast, a major challenge is to understand and overcome the barriers responsible for the diminished immunogenicity and efficacy of the same enteric vaccines in underprivileged populations in developing countries. Success in developing vaccines against some enteric pathogens has heretofore been elusive (e.g., *Shigella*).[360] Therefore, there is an urgent need for vaccines that induce effective and long-lasting intestinal immunity against diarrheal infections, especially during infancy and early childhood. Mucosal vaccines would be appropriate for a number of pathogens. These include pathogens that are noninvasive, such as *Vibrio cholerae* and ETEC; pathogens that produce gut inflammation, such as *Shigella* and rotavirus; and pathogens that invade through the intestine and enter the systemic circulation, such as *Salmonella typhi*, poliovirus, and human immunodeficiency virus. Although the first category may need a mucosally administered vaccine for adequate protection, especially in immunologically unprimed individuals such as infants and young children, the latter, more invasive infections can probably be prevented by vaccines given either mucosally or parenterally or by a combination of such routes. Although 30 or more parenteral vaccines are licensed, only a handful of oral vaccines are licensed: oral live attenuated typhoid vaccine, oral inactivated cholera, oral live attenuated cholera CVD 103-HgR, oral live attenuated rotavirus, and oral polio virus.[117] Many oral vaccines (e.g., poliovirus, rotavirus vaccine, live attenuated cholera vaccine CVD 103-HgR, and *Shigella flexneri* 2a SC602 vaccine) have performed poorly in developing countries when compared with industrialized countries, a finding attributed mainly to chronic environmental enteropathy, also called tropical enteropathy, which is characterized by disturbances of digestive and absorptive functions. Factors that may contribute to chronic environmental enteropathy include poor sanitation, intestinal flora overgrowth, and histologic changes characterized by inflammation and blunting of small intestinal villi leading to malabsorption. Children living under extreme poverty are especially sensitive.[117]

Rotavirus Vaccine

The first rotavirus vaccine licensed in the United States was associated with an increased rate of intussusception, resulting in its withdrawal from the market within 14 months of being licensed.[325,391] Two new vaccines have recently been shown to be safe and effective in protecting young children against severe rotavirus gastroenteritis and are now marketed worldwide.[400,476] In February 2006, a bovine-based pentavalent rotavirus vaccine[476] was licensed by the U.S. Food and Drug Administration for use in infants in the United States[18,83] as a three-dose vaccine administered orally at 2, 4, and 6 months of age, with all doses administered by the time the child reaches 32 weeks of age. Later, a two-dose orally administered, attenuated monovalent G1P[8] human rotavirus vaccine[400] was recommended by the U.S. Advisory Committee on Immunization Practices[110] and now is available in many countries throughout the world. Before routine rotavirus vaccination was recommended, rotavirus diarrhea caused an estimated 400,000 visits to physician's offices, 200,000 emergency department visits, 55,000 hospitalizations, and 20 to 60 deaths annually among children younger than 5 years of age in the United States.[156,173,489] Since the introduction of rotavirus vaccine, diarrhea-associated health care utilization and medical expenditures for U.S. children have decreased substantially.[109,367,482] Rotavirus vaccines have reduced the health burden of rotavirus gastroenteritis in both developed and developing countries.[122,393] It is hoped the diffusion of the vaccine use in low-income countries, endorsed by the WHO, will have a substantial impact on diarrheal overall burden of disease.[361,457]

Vaccines for Enteric Bacteria

Although several strategies have been used to develop vaccines targeting shigellosis, none has been licensed for use outside China. Owing to the wide range of *Shigella* serotypes and subtypes, there is a need for a multivalent vaccine representing prevalent species and serotypes. Strategies for *Shigella* vaccine development include live attenuated, conjugate, broad-spectrum, and proteosome-based vaccines. The greatest barrier to the use of vaccine against shigellosis in developing areas is a poor immune response to oral vaccines in children who have minimal maternal antibodies.[277] Several nonliving *Shigella* vaccines are currently at different stages of development and show substantial promise.[251] In relation to cholera, the availability of new oral vaccines and supporting data have prompted the WHO to recommend vaccination be used with other prevention and control strategies where disease is endemic and their use should be considered in outbreak situations. New variant strains appear to cause more severe clinical disease and may be displacing earlier seventh pandemic organisms as the major cause of cholera. Licensed newer-generation oral vaccines have proven to be well tolerated, protective (including against new variant strains), and affordable and offer a new tool to control cholera.[126] Finally, no effective vaccine for ETEC is available. Several inactivated and live candidate ETEC vaccines consisting of toxin antigens, alone or together with colonization factors, have been evaluated in clinical trials. Intense efforts are in progress to try to improve the immunogenicity of different available candidate vaccines, particularly in children, as well as to develop new types of ETEC vaccines.[448]

CHAPTER 45

Antibiotic-Associated Colitis

Robin Schmucker • Kristina Bryant

More than 130 million courses of antibiotics are prescribed in the United States each year, and diarrhea is a common side effect of antibiotic therapy. *Clostridium difficile* is the most common infectious cause of antibiotic-associated diarrhea, accounting for 15 to 25 percent of cases.[8] According to a 2012 report from the Centers for Disease Control and Prevention, the incidence, mortality, and medical care costs of *C. difficile* infection (CDI) have reached "historic highs," in part, because of the emergence of a hypervirulent stain of *C. difficile* identified as North American pulsed-field type 1 (NAP1).[21] Although most cases of CDI have traditionally occurred in hospitalized adults, infections are reported with increasing frequency in children.[54,74,103] CDI is recognized as a common cause of health care–acquired infection, but community transmission is also identified.[21]

HISTORY

In 1935, Hall and O'Toole described the identification of a new, anaerobic, gram-positive, spore-forming bacillus in the stools of 4 of 10 healthy, breast-fed neonates. They named it *Bacillus difficilis*, in recognition of the fact that the organism was difficult to isolate and study in the laboratory. *B. difficilis* was noted to be highly pathogenic in guinea pigs and rabbits; guinea pigs inoculated subcutaneously with the bacteria commonly developed convulsions, which the investigators attributed to a soluble exotoxin isolated from broth culture filtrates.[42] A link between intestinal colonization and illness in human infants was much less clear, although the authors postulated a potential association with occult blood in the stools of neonates or convulsions of unexplained origin. Neither association was proved, and, for decades, *B. difficilis* was thought to be a harmless, intestinal commensal in infants.[6] The role of *C. difficile* as a human pathogen was finally elucidated in the 1970s when toxin-producing *Clostridia* were isolated from the stools of adult patients with clindamycin-associated pseudomembranous colitis.[7]

ETIOLOGY AND PATHOGENESIS

Over the past decade, cases of CDI have increased in both frequency and severity. From 2000 to 2009, the number of hospitalized patients with CDI doubled.[21] Deaths attributable to CDI increased from 3,000 deaths per year during 1999 to 2000 to 14,000 during 2006 to 2007; more than 90% of the deaths occurred in individuals 65 years of age or older.[41] The increased incidence and mortality of CDI in adults has been attributed in large part to the emergence of spread of a hypervirulent, fluoroquinolone-resistant strain of *C. difficile*. The NAP1 strain produces more toxin A (TcdA) and toxin B (TcdB) than historic strains. The role of a third toxin, the binary toxin, is less clear but may contribute to enhanced virulence of toxin A and toxin B.[48]

Antibiotic use remains a principal risk factor for the development of CDI. The risk of CDI increases 7- to 10-fold during a course of antibiotics and for 1 month after antibiotic discontinuation.[43] Although the earliest reports of pseudomembranous colitis were associated with administration of clindamycin, nearly every antibiotic class has been implicated in the development of CDI, particularly cephalosporins, other β-lactam antibiotics, and fluoroquinolones. Diarrhea typically begins during antibiotic use or up to 30 days after antibiotic therapy.[87] Symptoms may occur after a single dose of an intravenous antibiotic.[57] Other risk factors for the development of CDI in adults include age older than 65 years, increased severity of underlying illness, prior hospitalization, gastrointestinal surgery, and use of feeding tubes.[10] Proton-pump inhibitor use has been associated not only with an increased risk of CDI but also with increased complication rates and increased mortality.[26,71,97]

CDI has historically been less common and less severe in children. However, over the past decade, rates of CDI in children have increased in both hospitals[54,74,103] and the community.[9] Moreover, CDI has been reported in children previously thought to be at low risk for the disease, including those without prior antibiotic or hospital exposure, as well as infants.[20]

Forty to 70 percent of asymptomatic, healthy newborns may be colonized with *C. difficile* in the first 10 to 28 days of life; colonization rates decrease to 3 to 10 percent by the second year of life.[47,49] Rates of *C. difficile* colonization in children older than 2 years of age approximate those in healthy adults and may be as low as 2 to 3 percent.[5,8,50]

Colonization occurs with both toxin-producing and nontoxigenic strains.[61] Factors associated with increased colonization rates in infants include longer duration of hospitalization, hospitalization in an intensive care setting, low birth weight, and formula feeding.[47] Even with a large number of toxigenic *C. difficile* bacteria and high levels of toxin A and B, infants usually remain asymptomatic,[65] and most studies have failed to show an epidemiologic association between colonization and disease in infants younger than 1 year of age. For example, in a study of outpatient children, *C. difficile* was isolated from 7% of patients with diarrhea and 14.8% of healthy controls. Children with *C. difficile* were younger than children without the organism (mean age 8.2 to 9.8 months).[11] *C. difficile* was isolated with equal frequency in healthy Swedish children 1 week to 1 year of age (17%) and children younger than 6 years with diarrhea (18%).[88] Most controlled studies in neonatal intensive care units corroborate high rates of asymptomatic colonization in young infants. *C. difficile* toxin was recovered from the stools of 55% of patients in one neonatal intensive care unit, but signs of enteric disease, including necrotizing enterocolitis, occurred with equal frequency in both toxin-positive and toxin-negative infants.[27] Although severe CDI has occasionally been reported in young infants, especially those with underlying gastrointestinal disease, it has historically been thought to be rare.[79]

Coincident with the emergence of the epidemic NAP1 strain, the epidemiology of CDI in children may be changing. In a study that included 21 free-standing children's hospitals, CDI increased 53% in hospitalized children between 2001 to 2006, from 2.6 cases to 4.0 cases per 1000 admissions.[54] Twenty-six percent of the children treated for CDI were younger than 1 year of age, and 5 percent were newborns. An analysis of two large administrative databases demonstrated a nearly twofold increase in CDI-associated hospitalization between 1997 and 2006.[103] Children younger than 1 year of age had the second highest rate of CDI hospitalizations. Investigators acknowledged that their study methodology precluded an assessment of whether these children had true CDI or *C. difficile* colonization in the setting of diarrhea attributable to another cause. Nevertheless, significant increases in CDI in hospitalized children have been documented, even when children younger than 1 year of age are excluded.[74]

C. difficile is a common health care–acquired pathogen, and most cases of CDI are health care associated.[21] In a prospective cohort study of children younger than 18 years of age, *C. difficile* was the most common cause of health care–associated diarrhea, occurring in 32 percent of cases.[60] Outbreaks of CDI among hospitalized pediatric patients are well documented.[17,37,67] Nevertheless, several studies have documented the importance of CDI in ambulatory settings. In a prospective cohort study of children presenting for outpatient care for diarrhea, nearly 8% were found to be positive for *C. difficile* toxin; other bacterial pathogens were identified in approximately 5 percent.[24] In a similar study of children presenting to an emergency department with diarrhea, 6.7 percent were positive for *C. difficile* toxin.[56] A 5-year retrospective study performed at a tertiary care children's hospital revealed an approximate 2.5-fold increase in the rates of community-acquired CDI in children who visited the emergency department.[9] Daycare center outbreaks of *C. difficile* have also been reported.[55]

Some of these changes may be related to the emergence of the epidemic NAP1 strain, which has been isolated from children with diarrhea.[53,85,94] Nevertheless, it is not yet known if the NAP1 strain is associated with more severe disease in children, as it is in adults. Ten percent of isolates from hospitalized children with CDI identified through the Canadian Nosocomial Infections Surveillance Program between November 1, 2004, and April 30, 2005, were the B1/NAP1/027 strain.[85] Children with the NAP1 strain were more likely to suffer complications from CDI than were children with other strains (29% vs. 6%; relative risk 4.6; 95% confidence interval 1.1 to 17.2; $p = .04$), although none died. Similar rates of NAP1 isolation were identified in a prospective study of children at two U.S. hospitals with CDI. NAP1 was not associated with increased disease severity.[53]

As in adults, antibiotic exposure is a risk factor for the development of CDI in children.[53,84] Use of amoxicillin-clavulanic acid for acute otitis media[69] and long-term antibiotic use for acne[34] have both been occasionally linked to the development of CDI in pediatric patients. In one study of hospitalized children, receipt of three or more antibiotic classes in the 30 days before diagnosis of CDI was a risk factor for severe disease.[53] Nevertheless, antibiotic use is not a prerequisite for the development of CDI in children. Severe disease has been reported in

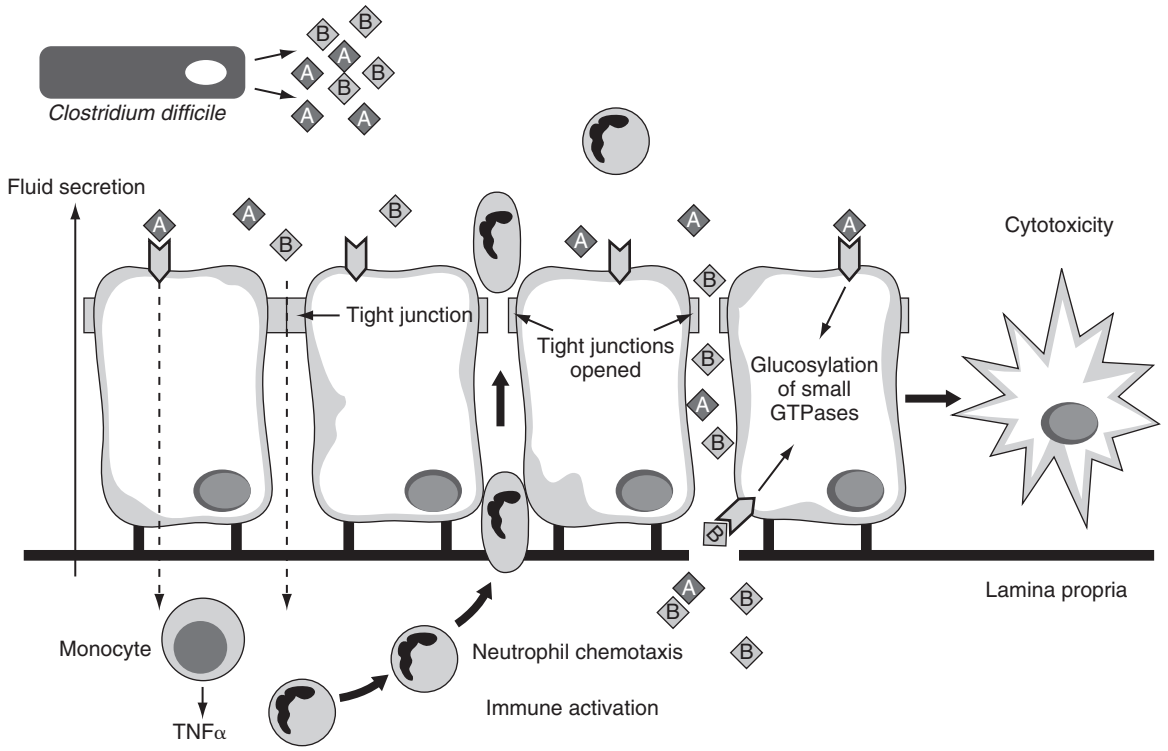

FIGURE 45-1 ■ Actions of *Clostridium difficile* toxins A and B on intestinal epithelium. (Courtesy Ian R. Poxton, Professor of Microbial Infection and Immunity, Medical Microbiology, University of Edinburgh School of Medicine.)

the absence of antibiotic exposure,[20] and in one study of community-acquired CDI, 43 percent of patients lacked a history of antibiotic use.[9]

Several studies have demonstrated that CDI is more common in boys.[74,79] Underlying gastrointestinal disease, particularly Hirschsprung disease, is a risk factor for severe, complicated CDI. Other risk factors for CDI in children include proton pump inhibitor use, solid organ transplant, inflammatory bowel disease, immune suppression, and cancer.[70,74,77,84] In a prospective study of 141 children undergoing chemotherapy for a solid tumor or lymphoma, 9 (6%) tested positive for *C. difficile* toxin A and were symptomatic.[19] Another study suggests that rates of *C. difficile* diarrhea in children after chemotherapy are as high as approximately 15 percent.[32] In an analysis of 3 years of data from the Kids' Inpatient Database (2000, 2003, 2006), children with cancer accounted for 21 percent of all CDI cases and rates of CDI were 15 times higher in children with cancer than in those without cancer.[89]

PATHOGENESIS

Ingestion of *C. difficile* spores and subsequent intestinal colonization precedes the development of CDI. In older children and adults, colonization is inhibited by normal intestinal flora, which is thought to compete for intestinal nutrients and space on the mucosal surface. Antibiotics, by altering normal flora, facilitate *C. difficile* colonization. Disease manifestations are related to toxin production; most toxigenic strains produce both toxin A and B.[80] Early animal studies suggested that toxin A was the major virulence factor, but recent studies have documented severe CDI caused by toxin A–negative, toxin B–positive strains.[1,66] Approximately 25 percent of *C. difficile* isolated by culture do not produce toxins[35] and are not clinically significant.

C. difficile toxins act at the level of the epithelial cells (Fig. 45-1) and produce effects by two main pathophysiologic pathways.[73,80] Toxin A and B cause the disorganization of actin microfilaments of the enterocyte cytoskeleton. The change in enterocyte structure leads to epithelial cell destruction and opening of tight junctions between enterocytes.[73,80] Toxin A also induces activation of neutrophils and results in local inflammation. Release of proinflammatory cytokines, including interleukin-6 and interleukin-8, occurs from enterocytes, causing further damage to the intestinal mucosa.[48,80] Both pathways lead to increased permeability of, and damage to, enterocytes, resulting in the clinical symptoms of *C. difficile*.[48]

Why young infants are commonly colonized with toxin-producing *C. difficile* strains yet rarely have symptoms is not yet completely understood. Colonization density does not appear to be important, because asymptomatic infants may have *C. difficile* colony counts as high as $10^{8.1}$ bacteria per gram of feces; these colony counts are similar to those in adults with pseudomembranous colitis.[47] Experiments in newborn rabbits suggested that protection against disease may result from lack of receptors for toxin A.[31] Interestingly, the appearance of receptors with age may be a species-specific phenomenon. Toxin receptors have been identified in the intestines of neonatal pigs, and these animals are susceptible to

disease.[51] The immaturity of the toxin receptor sites may also play a role in the absence of disease in neonates.[67]

Transmission of *C. difficile* is fecal-oral. The organism is generally spread by person-to-person contact or environment-to-person contact. Both modes of spread are important in health care environments, where *C. difficile* is shed in the environment by infected and colonized patients and occasionally from asymptomatic hospital personnel. Patients may acquire the *C. difficile* via the unwashed hands of health care workers, but direct or indirect transmission through contaminated objects and surfaces also occurs. *C. difficile* spores can survive for up to 5 months in the environment and are difficult to eradicate through routine cleaning and disinfection.[8,35,48] Objects likely to harbor organisms are those contaminated with feces and include toilet seats, sinks, and scales, but *C. difficile* can also be isolated from the hands and feces of asymptomatic hospital personnel.[35] Stethoscopes may be vectors for *C. difficile* transmission when not effectively cleaned after use on a patient with CDI.[98] Electronic rectal thermometers have also been implicated in hospital spread of *C. difficile*.[15]

Foodborne transmission has been postulated as a source of *C. difficile* spread in the community. Although *C. difficile* spores have been recovered from retail food products, there is limited evidence to link contamination of food to human illness.[39] Likewise, the role of zoonotic transmission has been explored because *C. difficile* is known to be both a pathogen and a commensal organism in domestic and food animals. To date, no study has convincingly demonstrated human *C. difficile* infection as a result of animal contact, although further research is needed.[39]

CLINICAL MANIFESTATIONS

C. difficile infection can cause a broad spectrum of disease from asymptomatic colonization or mild diarrhea to severe diarrhea, pseudomembranous colitis (PMC), toxic megacolon, and death.[6,96] Most commonly, *C. difficile* infection results in watery diarrhea in 90 to 95 percent of cases and bloody diarrhea in 5 to 10 percent.[57] Most pediatric patients develop self-resolving diarrhea associated with fever, abdominal pain and cramps, and abdominal distention, with or without bloody diarrhea, but some patients progress to PMC or chronic diarrhea, causing failure to thrive.[93] If severe disease develops, anasarca can occur because of protein-losing enteropathy.[6] Chronic diarrhea secondary to *C. difficile* can occur without evidence of colitis.[87] Uncommon complications of severe disease include gastrointestinal perforation, pneumatosis intestinalis,[53] or rectal prolapse.[45]

Mucoid stools are a hallmark of PMC.[57] PMC lesions almost always affect the colon, but involvement of the small intestine has been reported in adults.[46] Focal necrosis and inflammation are initially found in PMC lesions, but these can progress to extensive involvement of the colon covered by confluent pseudomembranes.[6] Although uncommon, fulminant colitis occurs and can lead to bowel perforation, peritonitis, and a high mortality rate.[58]

The role of *C. difficile* in the pathogenesis of necrotizing enterocolitis (NEC) among infants has been debated. Early studies reported no difference in colonization with *C. difficile* among infants with NEC and those without NEC.[101] A prospective study of 50 preterm infants also demonstrated that *C. difficile* colonization was not associated with a higher incidence of NEC.[33] In a retrospective cohort study of children with *C. difficile*–toxin positive stool specimens, 50 percent of 22 patients in a neonatal intensive care unit had suspected or confirmed NEC, although causality was not proved.[9]

In adults, *C. difficile* colitis has been reported to mimic acute peritonitis with fever, leukocytosis, and signs and symptoms of peritonitis on physical examination.[28,72,83,96] Rare extraintestinal manifestations of *C. difficile* include bacteremia, sepsis, visceral abscesses, pleural involvement, and reactive arthritis. Most cases of *C. difficile* bacteremia are usually polymicrobial with other bowel flora being isolated. The mortality rate of bacteremia is low.[46]

LABORATORY STUDIES

Stool culture is rarely used in clinical practice for the diagnosis of CDI. Although culture is highly sensitive, it requires selective media because it yields both toxigenic and nontoxigenic strains of *C. difficile*. Isolates must be tested for the presence of toxin genes or the expression of toxin gene proteins before the diagnosis of CDI can be confirmed.[58,62] Stool culture is generally reserved for epidemiologic investigations.[23]

The cell cytotoxicity neutralization assay (CCNA) has historically been considered the "gold standard" for the diagnosis of CDI and involves the addition of a diluted, buffered, and filtered stool sample to a monolayer of cultured cells. A positive CCNA test requires cytopathic changes in 50 percent or more of cells.[59] Although this test is highly specific, its sensitivity may be as low as 67 percent. Other limitations of CCNA include the need for skilled personnel to interpret the findings in tissue culture, the subjective nature of test interpretation, and an approximate 72-hour turn-around time.[18,59]

Enzyme immunoassays (EIAs) to detect toxin A and B or the glutamate dehydrogenase (GDH) antigen are commonly used for the clinical diagnosis of CDI. EIAs offer the advantages of rapid turn-around time, ease of use, and lower cost,[2,67,102] compared with CCNAs. EIAs for toxin A or toxins A and B have a reported sensitivity of 60 to 70 percent and specificities in the 90-percent range.[18] However, positive tests should be interpreted with caution in children because both lower sensitivity and specificity have been observed.[64,95] In one study of hospitalized children, the positive predictive value of a positive EIA was only 64 percent; one third of all positive EIA tests were ultimately found to be falsely positive.

In general, EIAs for GDH offer improved sensitivity but lower specificity because GDH is present in both toxigenic and nontoxigenic strains of *C. difficile* as well as other *Clostridium* species. The high negative predictive value of the GDH assay makes it useful as a screening tool.[18]

TABLE 45-1 **Laboratory Tests to Diagnose *Clostridium difficile* Infection**[59]

Testing Method	Sensitivity	Specificity	Advantage(s)	Disadvantage(s)
Culture	High	Low	Often considered gold standard	Long turn-around time; no differentiation between toxigenic and nontoxigenic strains
Cell cytoxicity neutralization assay (CCNA)	Moderate	Moderate to high	Highly specific	2 to 3 day turn-around time; requires skilled experts to interpret
Enzyme immunoassays for toxin detection	Low to moderate	High	Inexpensive; quick turn-around time; easy to perform	Overall low sensitivity
Enzyme immunoassay for glutamate dehydrogenase (GDH)	High	Low	Quick; useful for screening purposes	Low specificity; no differentiation between toxigenic and nontoxigenic strains
Nucleic acid amplification tests	High	High	High sensitivity and specificity; quick turn-around time; easy to perform	Expensive; increased detection of asymptomatic colonization

Nucleic acid amplification tests (NAATs) that detect toxin A *(tcdA)* or B *(tcdB)* genes, often by polymerase chain reaction, are increasingly available. Although expensive, these tests are rapid, specific, and more sensitive than EIAs.[25,64]

Because no single diagnostic test is presently optimal for the diagnosis of CDI (Table 45-1), some laboratories have adopted a multistep, diagnostic algorithm for stool testing. In one approach, stools are initially screened with a rapid immunoassay that can detect GDH and toxins A and B. Specimens that test both positive or negative for both GDH and toxin are immediately reported as positive or negative for toxigenic *C. difficile*. GDH-positive but toxin-negative specimens are subject to further testing by either a nucleic NAAT or CCNA.[18,59] The sensitivity and specificity of this approach in adult populations has been reported from 98 to 100 percent and 88 to 97 percent, respectively.[18] In a tertiary pediatric population, the sensitivity of the GDH-based algorithms was less but still superior to screening by toxin immunoassay (81% vs. 56%).[75]

Stool specimens submitted for *C. difficile* testing should be fresh and of liquid consistency. Specimens should be stored at less than 4° C because toxin rapidly degrades at room temperature.[23] Approximately 90 percent of patients can be diagnosed with CDI on a single stool sample and do not need repeat stool testing, because it does not increase diagnostic yield significantly and is not cost effective.[25] Because asymptomatic colonization is common in children younger than 1 year of age, testing for *C. difficile* should not be performed routinely in this age group and other causes for diarrhea should be sought.[59]

Leukocytosis, thrombocytosis, and hypoalbuminemia are commonly present in CDI. A leukocyte count greater than 15,000 cells/μL and a platelet count exceeding 400,000 cells/μL are more common in patients with CDI as compared to those without CDI.[76] Leukocytosis may be an early finding of CDI among hospitalized patients, even in the setting of mild or absent symptoms of colitis.[16,100] The presence of fecal leukocytes is an insensitive method for CDI screening.[82]

In seriously ill children in whom CDI is suspected but cannot be proved by standard laboratory testing, colonoscopy or sigmoidoscopy may be helpful. If pseudomembranes are found and clinical symptoms are consistent, the diagnosis of CDI can be made because almost all cases of PMC are caused by *C. difficile*. On examination, PMC has a characteristic appearance of yellowish white, raised plaques that are usually 2 to 10 mm in diameter.[67] Among infants with CDI, nonspecific colitis and not characteristic pseudomembranes are commonly found by endoscopy.[4]

Other radiographic modalities may provide supplemental data to aid in the diagnosis of CDI. Plain abdominal radiographs in patients with PMC may demonstrate colonic ileus, small bowel ileus, ascites, and/or nodular haustral thickening.[12] Abdominal computed tomography (CT) can be performed, but severity of colitis present on CT does not always correlate to clinical disease severity, and CT findings are less specific when compared with laboratory and clinical findings. Abnormalities on CT include nodular haustral thickening, colonic wall thickening, ascites, and pericolonic edema.[67] Abdominal ultrasonography has also been used to aid in the diagnosis of CDI because bowel wall thickening can be visualized.[81]

DIFFERENTIAL DIAGNOSIS

CDI must be distinguished from diarrhea that occurs as an adverse effect of antibiotics, other medications, or enteral nutrition, as well as diarrhea from other infectious causes. Viruses, for example, account for most cases of health care–associated diarrhea. *C. difficile* infection should be considered in hospitalized patients who develop diarrhea and who have had exposure to antibiotics.[60] Other bacteria that have occasionally been associated with antibiotic-associated diarrhea include *Staphylococcus aureus*, enterotoxin-producing strains of *Clostridium perfringens*, *Salmonella* species, and *Klebsiella oxytoca*.[6] Cytotoxin-producing *K. oxytoca* was recently reported as a cause of antibiotic-associated hemorrhagic colitis

(AAHC) in children.[44] In contrast to the diarrhea associated with CDI, the diarrhea associated with *K. oxytoca* AAHC is always bloody. Colitis is typically segmental and concentrated in the right colon; pseudomembranes are usually absent. AAHC is most commonly associated with exposure to amoxicillin-clavulanate.[44]

The differential diagnosis of community-onset diarrhea is broad compared with diarrhea with onset in the hospital setting. Bacteria, viruses, and parasites can all cause diarrhea in children, although viruses are still the most common.[24] Common causative viruses include astrovirus, adenovirus, and norovirus.[56] The incidence of rotavirus gastroenteritis has decreased with routine childhood immunization against this pathogen, but infections still occur.[91] Common bacterial causes of community-onset diarrhea, including *Escherichia coli*, *Campylobacter*, *Salmonella*, *Shigella*, and *Yersinia*, can be diagnosed by stool culture.[38,56] Like *C. difficile*, *Giardia intestinalis* can cause acute or protracted watery diarrhea. When clinical symptoms suggest CDI, testing should be considered even without a history of antibiotic use, especially in ambulatory patients. CDI in the absence of prior antibiotic exposure is more common in the community setting than the hospital setting and has been reported in 24 to 60 percent of patients with community-associated CDI.[30]

Inflammatory bowel disease, either Crohn disease or ulcerative colitis, should be considered in the setting of relapsing CDI or if colitis persists despite treatment.[13] In children previously diagnosed with inflammatory bowel disease, diarrhea and abdominal pain may be related to progression of inflammatory bowel disease and not CDI.[68]

TREATMENT

Among children with mild disease who do not require antimicrobial therapy, symptoms usually resolve within 7 to 10 days. Those with prolonged symptoms or more severe disease will require antimicrobial interventions.[14] Evidence-based guidelines have been published for the treatment of CDI in adults.[22] The American Academy of Pediatrics has made similar recommendations for the treatment of children and adolescents.[3] If possible, precipitating antibiotics should be discontinued. At least 10 days of oral or intravenous metronidazole (30 mg/kg/day in four divided doses, maximum 2 g/day) is recommended as initial treatment for most children and adolescents with CDI. Oral vancomycin (40 mg/kg/day in 4 divided doses, maximum 2 g/day) is generally reserved for patients with severe disease. Intravenous metronidazole in combination with vancomycin by mouth or nasogastric tube has been recommended for adults with severe CDI complicated by hypotension, shock, ileus, or megacolon; vancomycin may be administered rectally in cases of complete ileus.[22] These recommendations may have applicability for children with severe, complicated disease. Intravenous vancomycin is not effective for the treatment of CDI. Colectomy may be required for treatment of severe, complicated cases.

Relapse occurs in up to 20 to 30 percent of patients who initially improve with treatment with either metronidazole or vancomycin.[36] Most patients respond to a second course of the same treatment. A tapering and/or pulsed regimen of oral vancomycin has been recommended for adults who develop a second recurrence of CDI.[22]

In 2011, the U.S. Food and Drug Administration approved the use of fidaxomicin for the treatment of CDI in adults.[99] This monocyclic antibiotic acts as an RNA polymerase inhibitor and is bactericidal against *C. difficile*. In a large, multicenter randomized phase III trial, fidaxomicin was noninferior to vancomycin for the treatment of CDI (clinical cure 88.2% vs. 85.5%). However, recurrence of CDI within 4 weeks of clinical cure was significantly less in fidaxomicin-treated patients.[63] Published data in children are lacking.

Because perturbations in the normal bacterial flora of the gastrointestinal tract play a crucial role in the development of CDI, adjunctive therapies that promote the restoration of normal flora have received increasing attention. In fecal microbiota transplantation (FMT), stool from a healthy volunteer is administered to a patient with severe or relapsing CDI in an effort to restore normal intestinal flora.[52] FMT may be delivered by enema, colonoscopy, nasogastric tube or nasojejunal tube. Although randomized, controlled trials are lacking, data from case reports and case series suggest that symptoms resolve in more than 90% of patients treated with FMT.[52]

Probiotics have been studied alone or in combination with antibiotics for the treatment of CDI. One study of adults 18 years of age or older demonstrated that *Saccharomyces boulardii* administered in combination with high-dose vancomycin (2 g/day) decreased recurrences compared with vancomycin administered with placebo (16.7% vs. 50%).[86] Other clinical trials have failed to show a benefit of probiotics in treatment or prevention of CDI in adults.[78] Probiotic treatment of children with CDI has not been well studied.[92]

PREVENTION AND CONTROL

Because CDI is commonly precipitated by antibiotic therapy, judicious use of antibiotics is essential. Antimicrobial stewardship programs that reduce the use of broad-spectrum antibiotics have been linked to reductions in CDI in hospitalized patients.[90]

Contact precautions, in addition to standard precautions, are recommended for hospitalized patients for the duration of the illness.[3] Contact precautions include placement in a single-patient room when feasible, donning of gown and gloves by health care personnel before room entry, and hand hygiene after glove removal. The most appropriate method of hand hygiene when caring for patients with CDI has been the subject of some debate. Evidence-based guidelines published by the Infectious Disease Society of America (IDSA) and the Society for Healthcare Epidemiology of America (SHEA) recommend the preferential use of soap and water for hand hygiene over alcohol-based hand hygiene products only in outbreak settings,[22,29] while the AAP recommends soap and water routinely when caring for patients with CDI.[3]

The IDSA/SHEA recommendations may seem counterintuitive. Alcohol does not kill *C. difficile* spores. Additionally, in several studies, hand washing with soap and water was more effective than use of alcohol-based products in removing *C. difficile* spores from the hands of volunteers inoculated with the pathogen. Nevertheless, there are no data to support an increase in CDI with the use of alcohol-based hand hygiene products, nor are there studies that demonstrate a decrease in CDI when soap and water is used for hand hygiene. The recommendation to use soap and water for hand hygiene when caring for a patient with CDI in an outbreak setting is based on expert opinion.[22,29]

Appropriate environmental cleaning and disinfection of patient rooms and medical equipment are considered important measures in preventing health care–associated spread of *C. difficile*. Because quaternary compounds that are commonly used as hospital disinfectants are not sporicidal, chlorine-containing agents (e.g., household bleach diluted 1 : 10 in water) are recommended for cleaning in settings with increased rates of CDI.[22,29]

Measures to prevent the transmission of CDI in the community are less well defined, but include judicious antibiotic use. Children with *C. difficile* diarrhea should be excluded from daycare centers for the duration of illness.[3]

The observation that serum antibody levels against toxin A and B are associated with protection against recurrent CDI has fueled interest in the development of *C. difficile* vaccine. Although no vaccine is currently available for the prevention of CDI, in a recent phase I study, an adjuvanted *C. difficile* toxoid vaccine induced antibodies against toxin A in all healthy adult volunteers; some also developed antibodies against toxin B.[40]

CHAPTER 46

Whipple Disease

Zev Davidovics • Mark A. Gilger

Over the past 20 years there has been an explosion of knowledge about Whipple disease. It is now known that Whipple bacillus causes not only classic Whipple disease, a rare, systemic bacterial infection that can be fatal without therapy, but also acute infection such as gastroenteritis, pneumonia, and bacteremia. In its most common form, Whipple disease affects white, middle-aged men, causing diarrhea, weight loss, abdominal pain, arthralgias, and fever. Although it is extraordinarily rare in children, its recognition may be crucial, because simple treatment with appropriate antibiotics may be curative and lifesaving.[28]

HISTORY

Whipple disease was described in 1907 by George Hoyt Whipple,[91] at that time an instructor in pathology at The Johns Hopkins University.[7] Whipple's description probably was not the first; Allchin and Webb apparently described a patient with "Whipple disease" in 1895.[59]

In Whipple's account, a 37-year-old medical missionary was admitted to The Johns Hopkins Hospital with low-grade fever, steatorrhea, and an abdominal mass. The patient had a 5-year history of sporadic migratory polyarthritis. These attacks of arthritis were associated with a gradual loss of weight and strength. His skin was pigmented with a brownish hue. Laboratory evaluation found severe anemia and an enormous number of fatty acid crystals in the stool. Explorative laparotomy revealed large, firm mesenteric lymph nodes, and a diagnosis of either Hodgkin disease or tuberculosis was made. The patient died 1 week later, and autopsy revealed marked fatty deposition within intestinal mucosa and the mesenteric and retroperitoneal lymph nodes. Other findings included polyserositis (peritonitis, pleuritis, and

pericarditis) and endocarditis. Histologic examination revealed infiltration of the lamina propria of the small intestine by large, foamy mononuclear cells that did not stain for fat. Fatty acids and triglycerides were found in dilated lymph channels. Silver stains of the mesenteric lymph nodes showed "great numbers of rod-shaped organisms" that resembled the tubercle bacillus. Whipple suggested that these bacillus-like organisms in the nodes could be the cause.

Whipple[91] reported "a hitherto undescribed disease characterized anatomically by deposits of fat and fatty acids in the intestinal and mesenteric lymphatic tissues." He concluded that the patient had "an obscure disease of fat metabolism," and proposed the term *intestinal lipodystrophy*.[21] Whipple recognized the most important features of this disease except for the involvement of the central nervous system (CNS). In 1949, Black-Schaffer showed that macrophages within the intestinal mucosa of patients with Whipple disease are stained intensely by the periodic acid–Schiff (PAS) method,[45] proving that the macrophages contained glycoprotein or mucopolysaccharide, not fat, as Whipple had suggested.

In 1992, Relman and colleagues[71] identified a gram-positive bacillus in association with Whipple disease by use of polymerase chain reaction (PCR). They reported a unique 1321-base-pair, 16S ribosomal RNA sequence amplified by PCR on intestinal and lymph node tissue from five unrelated patients with Whipple disease. They suggested that the responsible bacillus is a member of the Actinomycetes. Relman and colleagues[71] concluded that the phylogenetic relationships of the Whipple disease bacillus, the features of the illness, and its distinct morphologic characteristics provided sufficient grounds to propose a new genus and species name: *Tropheryma whippelii* from the Greek *trophe*, or "nourishment"; *eryma*, or "barrier," because of the malabsorption it causes; and *whippelii* (now *whipplei*), in honor of Whipple.

EPIDEMIOLOGY

Classic Whipple disease characteristically occurs in white middle-aged men. Its true incidence and prevalence are unknown because fewer than 1000 cases have been reported worldwide. It is an extremely rare disease in children,* with fewer than 10 cases reported. The youngest patient was a neonate,[17] and the oldest was 83 years old.[53] The peak age at presentation is 40 to 49 years.[27] In a literature review of 114 patients,[53] 88 percent were men and 12 percent were women. Most of these patients were white. Most patients reported as having Whipple disease are from continental Europe or the United States.[15] In an extensive review of 741 cases, Dobbins[23] found that most academic centers in the United States had records of three or four unreported cases. He estimated that for every published report at least two or three unpublished cases exist and that 1500 to 2000 individuals probably have had Whipple disease.[18]

Although classic Whipple disease is quite rare, the incidence of *T. whipplei*–related infection may be higher than previously thought. Raoult and associates[68] found stool PCR evidence of *T. whipplei* in 36 of 241 (15 percent) children with acute gastroenteritis but in none of 47 control subjects. Thirty-three percent of children with a positive stool PCR also had another identified diarrheal pathogen. The bacterial load in the children's stool was higher than in asymptomatic controls, and more in line with numbers found in classic Whipple disease. These children showed seropositivity with IgM during the acute infection and recovered without treatment within 2 weeks. *T. whipplei* has also been identified in patients with pneumonia[10] and bacteremia.[29]

The prevalence of asymptomatic carriage of *T. whipplei* varies by country and exposure.[28,31,32] For example, in stools, prevalence estimates range from 2 to 4 percent of the general population, 12 percent in sewer workers, and 44 percent in healthy children in Senegal.[28,31,32] *T. whipplei* has been identified in 0.5 to 30 percent of healthy adults in saliva and gingival plaque.[73,77,84] Such studies confirm the existence of asymptomatic carriage.

Etiology and Pathogenesis

Although humans are the only species to display clinical signs of *T. whipplei* infection, they are likely not the only reservoir. In a study of sewage water in Austria, *T. whipplei* was found by PCR in 17 of 46 (37 percent) of samples.[79] Transmission of *T. whipplei* is most likely fecal-oral. Among asymptomatic workers in those plants, 16 of 64 (25 percent) were PCR positive for *T. whipplei* in their stool. This compared to a baseline rate of 7 percent of PCR-positive stools in controls. A study in France identified an asymptomatic control population with PCR-positive *T. whipplei* in 4 percent in their stool.[31] Similar to the Austrian study, sewage workers had a higher carrier rate of 12 percent. The same study did not identify *T. whipplei* in the stool of monkeys or apes.

Classic Whipple disease is caused by an organism known as Whipple bacillus or *T. whipplei*.[27,53,67,91] Despite Whipple's account of "great numbers of rod-shaped organisms," culture of the organism was unsuccessful until more recently.[91] In 2000, Raoult and associates[67] reported that the bacterium *T. whipplei* had been cultured successfully from an aortic valve vegetation in a patient with prolonged endocarditis. The bacteria were isolated after inoculation in a human fibroblast cell line (HEL). Analysis by PCR confirmed that the 16S ribosomal RNA gene of the cultured bacterium was identical to the *T. whipplei* sequence. Subcultures of the bacterium also were obtained, and high-titer polyclonal antibodies against *T. whipplei* were produced. Such antibodies potentially may allow serologic diagnosis to become a reality.

T. whipplei may be a member of the actinomycetales,[71] which are gram-positive bacteria with DNA rich in guanine and cytosine.[92] The genus consists of actinomycetes, streptomycetes, and the nocardioforms.[16] *T. whipplei* seems to be related most closely to the four actinobacteria *Dermatophilus congolensis*, *Arthrobacter globiformis*, *Terrabacter tumescens*, and *Micrococcus luteus*.[71] Using so-called bootstrap analysis, some researchers have argued that the Whipple bacillus is only 67 percent associated with actinobacteria, far from the level needed for

*References 1, 2, 5, 12, 43, 87.

scientific conclusion.[81] The Whipple bacillus may represent another, separate, fourth line of descent with the actinomycetes. Amplification, cloning, and sequencing of a 620-base-pair fragment of *T. whipplei* heat shock protein led to the conclusion that *T. whipplei* is a member of the actinomycetales.[60]

Scant support exists for a primary humoral immunodeficiency in Whipple disease,[36] but stronger evidence exists for a distinct defect in the cell-mediated immune function. Dobbins[22] reviewed data of 30 patients with HLA-A and HLA-B locus typing and 47 patients with HLA-B27 typing. He found an increased incidence of patients who were positive for HLA-B27 (28%), even with absence of concomitant sacroiliitis. Other reports have failed to confirm the increased association with the HLA-B27 antigen.[3] Marth and associates[55] studied 27 patients with Whipple disease. They found a significantly reduced number of cells expressing the complement receptor 3 L-chain (CD11B), a reduced proliferation to phytohemagglutinin and to sheep red blood cells, and a hypoergic skin reaction. These findings indicated a defect of cell-mediated immunity.

In patients with active disease, the number of $CD8^+$ cells is increased, which results in a reduced CD4/CD8 ratio. Such defects of cellular immunity seem to persist in patients for several years, despite complete remission of the disease. Schoeden and associates[78] were able to culture *T. whipplei* in mononuclear phagocytes deactivated with interleukin (IL)-4, IL-10, and dexamethasone. IL-4 was found to be the crucial deactivating signal that rendered monocytes permissive for intracellular multiplication of *T. whipplei*. IL-4 is an immunoregulatory cytokine. Schoeden and associates[78] suggested that host factors, such as an imbalance in the T-helper 1 and T-helper 2 immune response, may contribute to the pathogenesis of Whipple disease.

Desnues and colleagues[19,20] reported a specific gene expression pattern associated with replication of *T. whipplei* in macrophages. *T. whipplei* organisms are killed by monocytes. The addition of exogenous IL-16 enabled *T. whipplei* to replicate in monocytes and increased bacterial replication in macrophages. *T. whipplei* replication in macrophages was completely prevented after blocking IL-16 activity with the use of anti–IL-16 antibodies. Untreated patients with Whipple disease were noted to have significantly higher circulating IL-16 than that of control subjects and patients treated for Whipple disease. They concluded that response of monocytes and macrophages to IL-16 likely is crucial for replication of *T. whipplei* to occur, in patients with Whipple disease.

Oral acquisition of the Whipple bacillus seems most likely, emphasizing greater involvement of the duodenum and proximal jejunum than the more distal small intestine.[27] Only three reports of siblings with this disease exist; contagious spread of Whipple disease seems unlikely.[41] *T. whipplei* has been identified free in the small intestine next to the glycocalyx of the enterocyte's microvilli, in epithelial cells, and in the lamina propria.[27] Even in patients with extraintestinal Whipple disease, the organism usually is identified in the small bowel.[27] The bacillus seems to spread through the lymphatics and through the systemic circulation[27,46,61] and then can involve several extraintestinal organs. *T. whipplei* can be seen faintly by light microscopy. The bacilli are seen best by transmission electron microscopy, which reveals a rod-shaped organism 0.2 μm wide and 1.5 to 2.5 μm long (Fig. 46-1). The ultrastructure of the wall of *T. whipplei* is similar to that of other gram-positive bacteria, with the exception of an additional surface membrane. This membrane is different from the outer membrane of gram-negative bacteria because it is thinner, has a symmetric profile, and has no PAS-positive components.[81] After the bacillus has been ingested by the macrophage, the degenerative process that occurs leads to the accumulation of bacterial remnants that are resistant to degradation. The polysaccharide-containing portion of the bacillus wall correlates with these remnants, and its progressive accumulation leads to the typical intramacrophagic inclusions. These inclusions are PAS positive and one of the key features in the histologic diagnosis of Whipple disease.[7] Biopsy specimens from the small intestine in patients with Whipple disease usually show characteristic changes. The intestinal villi are preserved,[27] but distortion of the architecture occurs.[36] A clubbed appearance of the intestinal villi[53] usually is present caused by the accumulation of foamy macrophages in the lamina propria.[27] The enterocytes may appear normal,[24,53] or they may show flattening and vacuolization and occasionally appear cuboidal (Fig. 46-2).[24,53] Lipid accumulation, with large fat droplets within the lamina propria and smaller droplets within and between the absorptive cells, occurs commonly.[53] In some instances, prominent, dilated lacteals are present.[27] Ectors and associates[24] reported reduced and absent lactase and major histocompatibility complex class II (HLA-DR) expression that normalized within 3 to 6 months of starting antibiotic therapy.

The characteristic feature of Whipple disease is the presence of PAS-positive, diastase-resistant macrophages.[41] These findings are not pathognomonic, however, because intestinal PAS-positive macrophages can be found in other conditions,[27] such as histiocytosis, melanosis coli, and *Mycobacterium avium-intracellulare*

infection, and even within macrophages in healthy individuals. The macrophages in Whipple disease do not stain with Ziehl-Neelsen.[24,41] A sickle-shaped appearance of the PAS-positive granules often is present in the macrophages of patients with Whipple disease.[53]

Sieracki and Fine[80] observed systemic involvement in the autopsies of five patients with Whipple disease. The sickle-shaped, PAS-positive macrophages were thought to be specific for Whipple disease, showing involvement of the entire gastrointestinal tract and the pancreas; diffuse involvement of the retroperitoneum and lymph nodes, the adrenals, the liver with sickle-form particles in Kupffer cells and in histiocytes, the brain, the heart, and the visceral pleura of the lungs; and minimal involvement of the genitourinary tract, skeletal muscles, and bone marrow. James and associates[46] examined the vessels of the gastrointestinal system and found abundant bacilli in the arteries of the small intestinal serosa and liver. They noted focal degeneration and fibrosis in the tunica media with arteritis and intimal proliferation. Rickman and coworkers[60] reported a case that confirmed the presence of *T. whipplei* in the vitreous of the eye.

T. whipplei produces a predominantly histiocytic inflammatory reaction, with infiltration by macrophages.[26] Noncaseating, epithelioid cell, sarcoid-like granulomas are located preferentially in peripheral lymph nodes and the liver.[18,26] These granulomas occasionally can be seen in different tissues, including three reports of granulomas in the intestinal tract.[26] Mesenteric lymph nodes often are strikingly enlarged.[15]

Electron microscopy can be useful, often revealing the presence of the rod-shaped bacterium (see Fig. 46-1).[28] Electron microscopy also shows intestinal macrophages containing bacteria with signs of lysis.[81] Silva and associates[81] described steps of a degradative process of the bacillus that starts with disorganization of the surface membrane and the thick outer wall. With the loss of intracellular material, bacterial ghosts composed of the three inner layers of the envelope are present. The two electron-dense layers of the cytoplasmic membrane become disorganized and solubilized, leaving the inner dense layer of the cell wall as the final bacterial remnant (Fig. 46-3).

TABLE 46-1 Clinical Presentations of *T. whipplei* Infection

Acute infection
Gastroenteritis
Bacteremia
Pneumonia
Asymptomatic carriage
"Classic" Whipple disease

Data from references 1-3, 12, and 13.

CLINICAL MANIFESTATIONS

The manifestations of *T. whipplei* infections now include at least three forms, "classic" Whipple disease; acute infection such as gastroenteritis and bacteremia; and asymptomatic carriage (Table 46-1).[19,20]

Acute Infection

Gastroenteritis

T. whipplei is associated with a mild acute gastroenteritis in young children.[68] Diarrhea typically lasts from 4 to 5 days and is associated with weight loss and 1 to 2 days of fever. Additional side effects include vomiting (55%), abdominal pain (25%), and bloody diarrhea (8%). The infection has no seasonality.

Bacteremia

In rural West Africa, *T. whipplei* was found by PCR in the blood of adults and children with unexplained fever.[29] Patients with *T. whipplei* bacteremia also have associated cough and sleep disorders. The bacteremia has seasonality, occurring primarily during the months of December

and January. Fevers are not commonly associated with gastrointestinal symptoms, and patients rarely have PCR-positive stool or saliva.

Pneumonia

Severe cases of pneumonia in adults and children are associated with *T. whipplei*.[10,44] PCR has detected *T. whipplei* in the bronchoalveolar lavage of mechanically ventilated patients in intensive care units. Initial presentations include aspiration pneumonia, community-acquired pneumonia, and ventilator-associated pneumonia. Duration of mechanical ventilation ranges from 3 to 81 days, and the mortality rate is high (33 percent).

"Classic" Whipple Disease

Whipple disease is viewed best as a multisystem illness. It usually manifests as arthralgias and then progresses to involve the gastrointestinal tract.[6] Malabsorption is the key feature of clinical disease, but no specific signs or symptoms for Whipple disease are known. The major symptoms and signs of Whipple disease are listed in Table 46-2. In children, failure to thrive, malnutrition, and chronic diarrhea appear most frequently. Abdominal distention, abdominal pain, and generalized lymphadenopathy may be found.[2] Response to antibiotic treatment may be dramatic, with rapid weight gain and resolution of symptoms.[5]

Gastrointestinal Tract

One of the most common symptoms is weight loss, which is found in 65 to 100 percent of patients.[15,25,27,37,53] Weight loss may be the only symptom.[12] Diarrhea is reported in 60 to 85 percent of patients.[15,27,37,53] The diarrhea usually is watery or fatty.[53] Several mechanisms have been proposed to explain the malabsorption and steatorrhea in Whipple disease.[27] Direct infection and secondary enterocyte dysfunction may prevent the esterification of fatty acids to triglycerides and inhibit the uptake of carbohydrates and amino acids. Blockage of transport of triglyceride-rich chylomicrons into lacteals may result from the deposition of foamy macrophages in the lamina propria. Lymphatic obstruction may occur by involvement of the mesenteric lymph nodes. Malabsorption and diarrhea tend to resolve within a few days after initiation of antibiotic treatment, whereas the lacteal dilation and PAS-positive macrophages can remain for months to years. Occult gastrointestinal bleeding frequently is found, but melena and gross gastrointestinal bleeding are rare. Hematemesis has been reported.[13] Endoscopy revealed diffuse hemorrhagic duodenitis with bleeding on contact.

Abdominal pain is experienced by 60 percent of patients.[15,27,37,53] The pain is nonspecific, is generally epigastric, and may be worse after meals.[53] Abdominal pain and anorexia may lead to reduced calorie intake and further weight loss.[27] Abdominal distention occurs commonly and may be secondary to intra-abdominal lymphadenopathy or to thickening of loops of diseased intestine.[27,53] Ascites occasionally is seen and may be chylous, secondary to lymphatic obstruction.[12,27]

TABLE 46-2 **Major Symptoms and Signs in Whipple Disease**

	Cases (%)
Symptoms	
Weight loss	65-100
Chronic diarrhea	60-85
Arthralgia	65-80
Abdominal pain	60
Fever	10-55
Central nervous system–related complaints	10-40
Signs	
Malnutrition	90-95
Hypotension	70
Lymphadenopathy	55
Hyperpigmentation	45-55
Abdominal tenderness	50
Edema	30
Abdominal mass	20
Hepatomegaly	1-14
Splenomegaly	5-10
Ascites	8

Data from references 12, 26, 27, 45, and 48.

Joints

Arthralgia, the most frequent nongastrointestinal symptom in Whipple disease,[27,53] is present in 65 percent of adult cases.[53] Arthralgia may precede manifestation of gastrointestinal symptoms by many years or decades[27,49] and occurs less frequently in children. Generally, joint symptoms continue unchanged with the onset of gastrointestinal symptoms.[27] Acute migratory arthralgia or arthritis may last days or weeks[37,41,53] and may persist as the disease progresses. The involved joints, in decreasing order of frequency, are knees, ankles, hips, fingers, wrists, elbows, hands, and spine.[27] Examination may reveal joint pain, swelling, limited range of motion, and warmth.[76] Fever sometimes is present.[27] Spondylitis, with or without sacroiliitis, may develop.[5] Permanent joint destruction and deformity are uncommon occurrences but can be severe.[27,76] Arthrocentesis may reveal an inflammatory arthritis, with cell counts of 6000 to 75,000/mm^3, often with a polymorphonuclear leukocyte predominance.[27] Synovial biopsy may show PAS-positive macrophages.[27]

Central Nervous System

Whipple disease can be confined to the brain[74] but usually is accompanied by other manifestations.[37] CNS and neurologic manifestations, such as headache, diplopia, meningoencephalitis, depression, confusion, and personality changes, are uncommon manifestations[15,27,53] but may be significant.* The spectrum of potential CNS involvement is listed in Table 46-3.

*References 15, 27, 36, 53, 62, 64.

TABLE 46-3 **Central Nervous System Symptoms and Signs of Whipple Disease**

Ataxia
Confusion
Convulsions

Nystagmus
Ophthalmoplegia
Papilledema
Polydipsia
Ptosis
Pupillary abnormalities
Sensory loss
Sleep disorders
Slurred speech
Stiff neck
Tinnitus
Visual difficulties (diplopia, blurring)

Eye

Indirect involvement of the CNS and direct involvement of the eye can produce visual problems.[27] Ophthalmoplegia and diplopia can occur with involvement of cranial nerves III, IV, and VI.[24] Reduced visual acuity and papilledema can occur with compromise of the optic nerve.[27] Numerous ophthalmologic findings, including vasculitis, vitritis, optic atrophy, uveitis, chorioretinitis, vitreous opacities, glaucoma, keratitis, retinal hemorrhages, disk edema, and lacrimal duct obstruction, have been reported.[27,89,90] Rickman and associates[72] reported a case of ocular disease without marked CNS or gastrointestinal disease.

Skin

Hyperpigmentation of the skin in sun-exposed areas occurs in roughly half of cases.[36,53] The mechanism of hyperpigmentation is uncertain but is not related to adrenal insufficiency.[27] Subcutaneous nodules may be found and can reveal PAS-positive macrophages and bacilli on electron microscopy.[40]

Heart

The heart frequently is involved in Whipple disease. Endocarditis, myocarditis, pericarditis, pancarditis, and coronary arteritis have been found.[27,57,88] A blood culture–negative endocarditis may be caused by Whipple disease.[27] Chronic aortic regurgitation is the most common clinical finding of endocardial involvement.[27] Pericarditis with polyserositis (pleuritis, peritonitis) has been found.[35] The abnormalities on electrocardiogram are nonspecific but include first-degree atrioventricular block, left ventricular hypertrophy, sinus tachycardia, left bundle branch block, intraventricular conduction delay, old inferior wall infarct, and short PR interval.[36] Sossai and associates[83] reported a case of regression of a right bundle branch block after treatment with antibiotics, but the block spontaneously recurred 2 years later.

Skeletal Muscle

Skeletal muscle may be involved, diagnosed by electromyography or muscle biopsy.[85] Proximal muscle weakness occurs most commonly. Muscle biopsy reveals a nonspecific myopathy.

Lymph Nodes and Spleen

Whipple disease may involve any lymph node in the body.[27] Mesenteric lymph nodes frequently are involved, and splenomegaly is found in 5 to 10 percent of cases.[53]

Lungs

Cough, pleuritic chest pain, and dyspnea have been reported.[86] Pleural involvement may appear as a pleural rub. Pleural adhesions and granulomas have been reported at autopsy.[5,86] Chest radiography often reveals pleural thickening, parenchymal shadowing, and elevation of the diaphragm.[86] Lung function tests may show decreased lung volumes.[86]

Kidney

Renal involvement in Whipple disease is rare.[27] Granulomas have been found, however, as has focal glomerulonephritis.[48]

Blood

Anemia occurs commonly and usually is of a hypochromic, microcytic variety.[27,36,37] Macrocytic anemia caused by malabsorption of folate also may be seen. Leukocytosis, thrombocytosis,[63] and bone marrow involvement may be found.[69] Low serum iron concentration and an elevated erythrocyte sedimentation rate frequently are seen.[36] A single case of extraintestinal lymphoma in association with Whipple disease found at autopsy has been reported.[39]

DIAGNOSIS

Despite the successful culture of the organism in 2000,[67] no specific diagnostic tests have been developed. Anemia and low albumin level probably are most common, being found in approximately 90 percent of patients. Low serum iron and folate concentrations are seen in approximately 30 percent of cases. Hypokalemia, hypocalcemia, low cholesterol and carotene, prolonged prothrombin time, and increased transaminase levels are less common findings. Elevated fecal fat is found in more than 90 percent of cases. The D-xylose malabsorption test result frequently is abnormal.

Barium x-ray studies of the small bowel may show marked thickening of the mucosal folds and separation of bowel loops, suggesting a malabsorptive disease. These findings usually resolve completely with successful antibiotic therapy. For CNS Whipple disease, characteristic abnormalities seen on computed tomography of the brain include atrophy, focal gray matter lesions, hydrocephalus, and white matter alterations.[87]

A key feature in the histologic diagnosis of Whipple disease is the accumulation of periodic acid–Schiff-positive, diastase-resistant macrophages in the lamina propria of the small intestine.[5,36,54] These findings are not pathognomonic, and infection with *M. avium-intracellulare* must be excluded.[54] *T. whipplei* does not stain acid-fast,[54] whereas mycobacteria are identified readily. Small bowel involvement by *M. avium* complex can have endoscopic, histologic, and radiographic findings similar to those of Whipple disease.[66] Periodic acid–Schiff-positive macrophages occasionally can be seen in the mucosa of the large bowel and rectum in unrelated diseases, such as histiocytosis, and in benign conditions, such as melanosis coli and pneumatosis intestinalis.[54] Although electron microscopy can confirm the diagnosis by visualization of the characteristic bacillus,[37,81] immunohistochemistry has shown to be not only more efficient, but also more sensitive and specific than periodic acid–Schiff in the diagnosis and monitoring of *T. whipplei* infection.[4,50] Using a polyclonal rabbit antibody produced against *T. whipplei*, Baisden and associates[4] were the first to show sensitivity equal to periodic acid–Schiff without cross reactivity with other bacterial species.

Endoscopy of the small bowel may be helpful because characteristic lesions may be seen and biopsy specimens can be obtained. No clear data suggest where the intestinal specimens should be taken[54] because intestinal involvement usually is patchy. Random biopsy samples of the small bowel are suggested, beginning at the ligament of Treitz.[58] Endoscopic findings include yellow-white plaques and an erythematous, erosive, friable mucosa.[38]

PCR amplification may be used to detect and identify bacterial pathogens. To set up a PCR, the only prerequisite information is the nucleotide sequences flanking each end of the target.[70] PCR has become an important method for establishing the diagnosis of Whipple disease. It may be especially helpful if the histopathologic examination findings are normal or in patients with unusual extraintestinal involvement. Specific identification of *T. whipplei* can be achieved by amplification of the 1321-base-pair bacterial, 16S ribosomal RNA gene isolated from infected tissue.[71] Muller and associates[61] applied this PCR technique to show *T. whipplei* in peripheral blood mononuclear cells and cells derived from pleural effusion in a patient with Whipple disease. PCR techniques have been used to detect *T. whipplei* in erythrocytes,[52] cerebrospinal fluid,[7] and resected heart valves with infective endocarditis.[12,14,61]

Sloan and colleagues[82] reported another real-time PCR method using a 213-base-pair target sequence of the heat shock protein *(hsp65)* gene of *T. whipplei*. The sensitivity, specificity, and positive and negative values of this LightCycler real-time PCR were compared with the conventional 16S rRNA gene sequence PCR assay and were 98 percent (sensitivity), 99 percent (specificity), 94 percent (positive), and 100 percent (negative). The completion time of the LightCycler assay was approximately 5 hours, which was significantly less than the 2 to 3 days required for the traditional PCR assay.[82]

The diagnostic utility of PCR in Whipple disease is clear, but it cannot be taken as the sole basis for diagnosis. Ehrbar and associates[26] studied the specificity of PCR for *T. whipplei*. They performed elective gastroscopy on patients without known Whipple disease. PCR analysis was positive in 4.8 percent of duodenal biopsy specimens and 11.4 percent of gastric juice samples. Compared with the gold standard of histology and clinical signs, the specificity of PCR for *T. whipplei* was 95.2 percent for duodenal biopsy specimens and 88.6 percent for gastric juice. These findings suggest that *T. whipplei* or a closely related bacterium may be present in some people without known Whipple disease. Street and colleagues[84] detected *T. whipplei* DNA by PCR in the saliva of 35 percent of 40 healthy adults tested, which suggests that this organism can be an oral commensal.

In a study by Fenollar and associates[28], when real-time PCR detection of *T. whipplei* in saliva and stool were combined, the positive predictive value of the patient having Whipple disease was 95.2 percent. Additionally, if the bacterial load in the stool was more than 10^4 CFU/g, the positive predictive value increased to 100 percent. Conversely, classic Whipple disease was unlikely in patients with saliva or stool specimens negative for *T. whipplei* by real-time PCR, having a negative predictive value of 99.2 percent. The authors argue that following these negative results, additional specific investigations for classic Whipple disease could be stopped. Localized Whipple disease was poorly detected by PCR of the saliva and stool samples, with a sensitivity of only 58 percent.

TREATMENT

Antibiotics are the mainstay of therapy for Whipple disease.[15] In vitro antibiotic susceptibility testing using real-time PCR has identified penicillin, doxycycline, macrolides, ketolides, rifampin, aminoglycosides, teicoplanin, chloramphenicol, and trimethoprim-sulfamethoxazole (TMP-SMX) with activity.[8,9,56] Current antibiotic treatment strategies are empirical, based only on the accumulated anecdotal experience. Generally, response to antibiotics is good and often dramatic. Symptoms such as diarrhea quickly resolve, and weight gain is rapid. Several

TABLE 46-4 **Treatment of Whipple Disease: Initial Antibiotic Regimen and Relapse**

*Oral therapy.
†Includes 2 patients treated with TCN only in whom CNS relapse was the second relapse.
Data from Keinath RD, Merrell DE, Vlietstra R, et al. Antibiotic treatment and relapse in Whipple's disease: long-term follow-up of 88 patients. *Gastroenterology* 1985;**88**:1867–73.
CNS, central nervous system; PCN, penicillin; STM, streptomycin; TCN, tetracycline; TMP-SMX, trimethoprim-sulfamethoxazole.

antibiotics that have been tried alone or in combination include chloramphenicol, penicillin, streptomycin, ampicillin, TMP-SMX, erythromycin, and doxycycline.[15,27,34,37] Keinath and associates[47] analyzed the antibiotic response rate of 88 patients with documented Whipple disease. Thirty-one patients experienced relapse, with a mean time to relapse of 4.2 years after initial diagnosis. CNS relapse occurred in 13 of 88, and all CNS and cardiac relapses were late (Table 46-4). In addition to diagnosis, PCR may prove useful in the monitoring of response to antibiotic therapy.[42,65] Disease relapse may be secondary to genetic mutations in *T. whipplei*. Fenollar and associates[30] discovered amino acid changes in the *T. whipplei folP* gene, which encodes dihydropteroate synthase, the target of sulfonamides. Two amino acid positions, N4S and S234F, significantly predicted treatment failure to sulfamethoxazole.

All patients with Whipple disease should receive antibiotics that penetrate the blood-brain barrier.[47,75] Tetracycline and penicillin do not penetrate the blood-brain barrier well, unless the meninges are inflamed.[75] The preferred treatment in adults and children is TMP-SMX given orally twice a day for 1 year.[75] If the small bowel is involved, repeated small bowel biopsy is suggested at least 6 months to 1 year after treatment to document the disappearance of the bacillus. For patients who do not tolerate TMP-SMX, penicillin or ampicillin is recommended. Levy and associates[51] described a case of acquired resistance to TMP-SMX that responded to oral penicillin. Feurle and Marth[34] noted that TMP-SMX was more efficacious than tetracycline in inducing clinical remission of Whipple disease. They observed the development of aqueductal stenosis with hydrocephalus in a patient receiving TMP-SMX treatment, however, and indicated that even TMP-SMX is no safeguard against cerebral recurrence.

Treatment with IV antibiotics before a course of TMP-SMX may improve remission rates. In a randomized control trial, Feurle and associates[33] studied the use of ceftriaxone or meropenem IV for 2 weeks before initiating a 1-year course of TMP-SMX. At a 3-year follow-up, all 38 subjects, except for 1 with asymptomatic CNS infection with *T. whipplei*, had clinical and biopsy evidence of disease remission.

CNS relapse has a poor prognosis.[11,27,34,37,47] Feurle and Marth[34] suggested an experimental therapy for CNS recurrence with a highly active bactericidal compound, such as a third-generation cephalosporin, a quinolone, or intrathecal antibiotic therapy, that readily crosses the blood-brain barrier. In adult patients, Keinath and associates[47] recommended treatment with parenteral penicillin 1.2 million units daily plus streptomycin 1 g daily for 10 to 14 days, followed by TMP-SMX one double-strength tablet twice daily for 1 year. Because of the extreme rarity of the occurrence of Whipple disease in children, prudent management dictates long-term surveillance after resolution of symptoms.

Because Whipple disease is a malabsorptive disorder, the patient's nutritional needs must be assessed carefully. Specific attention must be paid to replacement of any vitamin or mineral deficiencies. Iron, folate, vitamin D, and calcium typically are given until the steatorrhea resolves.

CONCLUSION

T. whipplei appears ubiquitous in our environment but appears to only rarely cause disease. It is involved in not only classic Whipple disease but also acute infection and asymptomatic carriage. These findings suggest a genetic predisposition to classic Whipple disease, but causative genes or immune factors have not yet been identified.

SECTION **VII**

LIVER DISEASES

CHAPTER 47

Hepatitis

Daniel H. Leung • Leon L. Chen

Hepatitis, or inflammation of the liver, may be caused by a variety of infectious agents. Some agents, such as hepatitis A, B, C, D, and E viruses, are primarily hepatotropic and produce disease almost exclusively in the liver, whereas other agents, such as cytomegalovirus (CMV), Epstein-Barr virus (EBV), adenovirus, and the hemorrhagic fever viruses, produce hepatitis as part of a systemic or disseminated illness. With many infectious agents, hepatitis may be subclinical or silent, with very few, if any, signs or symptoms manifested in the patient. Symptomatic or clinical hepatitis may be acute or chronic at initial evaluation, and it may be associated with mild to even fulminant or fatal disease.[78] Children of all ages, both immunocompetent and immunocompromised, may contract infectious hepatitis, and the age and immune status of the host, as well as the history of exposure, may provide clues to identification of the most likely etiologic agent. Noninfectious causes such as autoimmune, storage, and metabolic disorders, exposure to toxins, or hypersensitivity reactions to medications or drugs are also important causes of hepatitis in children. Hepatic steatosis associated with childhood obesity and type 2 diabetes is a rapidly growing public health concern for our youth. Vasculitis, cardiac disease, hypoxic injury, or trauma also may damage the liver.

A general approach to an infant or child with hepatitis or hepatic dysfunction, from an infectious perspective, is presented in this chapter. Detailed information regarding the diagnosis and management of each particular pathogen can be found in the respective chapters in the section of this textbook dedicated to infections with specific microorganisms.

HISTORY

Originally described by Hippocrates in the second century BC, hepatitis has an ancient historical perspective. The earliest descriptions of outbreaks of hepatitis in the ancient world most likely involved hepatitis A virus (HAV), and it was known as epidemic *jaundice* and *catarrhal jaundice* or *acute yellow atrophy of the liver* if the disease was severe or fulminant.[25] The earliest recorded outbreak in the United States occurred in Norfolk, Virginia, in 1812.[11] During wartimes, outbreaks of "camp jaundice" or "field jaundice" occurred and probably were caused by HAV, yellow fever, or leptospirosis. Not until 1973 was the cause of "infectious hepatitis" determined to be a 27-nm, nonenveloped viral particle, originally designated enterovirus 72, now known as HAV.[45] Infection with hepatitis B virus (HBV) has a relatively more recent history. It probably was described originally in the late 1880s in an epidemiologic study published by Luerman in 1885 in Germany, where an outbreak of hepatitis in shipyard and warehouse workers who received smallpox vaccine contaminated with human material was associated with a prolonged form of hepatitis.[88] Other outbreaks of "serum hepatitis" associated with percutaneous therapies, such as gold used for rheumatoid arthritis or contaminated vaccines that were stabilized with human serum have been described.[1,14,69] In the early 1970s, the complete HBV infectious particle identified in serum was called the *Dane particle*. A specific serologic marker, originally called the *Australian (Au) antigen* (because it was discovered first in the blood of an Australian aborigine) and later became what is now known as hepatitis B surface antigen (HBsAg), was characterized and subsequently used to diagnose HBV.[16,87,130] Not long thereafter, in the mid 1970s, parenterally transmitted "non-A, non-B hepatitis" was described and subsequently identified in 1989 as hepatitis C virus (HCV).[23,70,131,152] The 1970s also marked the discovery of hepatitis delta virus (HDV), a "defective helper virus" that replicates only in the presence of HBV and is associated with chronic or fulminant hepatitis.[135,136] In the 1990s, another enterically transmitted non-A, non-B hepatitis virus was found to be associated with outbreaks of infectious hepatitis in developing parts of the world.[12,59] It was characterized originally as a calicivirus-like particle and subsequently named hepatitis E virus (HEV).[134] No doubt, as our medical knowledge evolves, even more viruses and other infectious agents associated with hepatitis will be discovered and named. Antiviral treatment of viral hepatitis is also now routine, and with the new millennium we also have entered an antiviral era for specific genomic targeted treatment of hepatitis B and C viruses.[38,54]

CLINICAL MANIFESTATIONS AND EVALUATION

Patient History

The clinical approach to evaluating and managing a child with hepatitis includes careful attention to the age of presentation; evolution of the initial signs and symptoms; history of exposure to potential pathogens, toxins, or medications; the presence of underlying conditions; and a family history of intravenous drug use or liver or metabolic disorders. Presenting symptoms in older children with acute hepatitis are nonspecific and may include fever, vomiting, anorexia or aversion to specific foods, change in taste and smell, lethargy and malaise, weight loss, dark urine, pale stool, jaundice, icterus, or even

pruritus. Abdominal pain is a common complaint, and it usually is mild, dull, or aching; located in the right upper quadrant; and unaffected by meals, body position, or defecation. Often, an antecedent viral syndrome or "flulike" illness is noted 7 to 14 days before the onset of hepatitis. Rarely, a "serum sickness–like syndrome" may occur at the onset of the illness, before jaundice occurs, and is characterized by fever, rash, and arthritis. In contrast, neonates rarely have signs and symptoms from infection with hepatotropic viruses and are more likely to have clinical disease with agents that cause congenital or perinatal infection, such as CMV, herpes simplex virus (HSV), rubella virus, parvovirus B19, or *Treponema pallidum*, especially if extrahepatic signs such as splenomegaly, skin lesions, microcephaly, or hearing loss are present. Neonates and young infants often become seriously ill with disseminated HSV, enteroviruses, or adenoviruses and show signs of acute, massive hepatocellular necrosis. These signs can include irritability or lethargy, jaundice, ascites, abdominal distention, hepatomegaly, acholic stools, anasarca, and coagulopathy. Patients from developing countries with a personal or maternal history of blood transfusions should be screened for HBV, HCV, and HDV and CMV, whereas previous attendance at summer camp or an institutional environment might warrant HAV screening. Recent treatment with antifungal azoles, antibiotics (macrolides, cyclines, isoniazid), antiepileptics, or even hepatotoxic over-the-counter medications such as acetaminophen may suggest drug-induced hepatitis.[133] Exposure of older children to feral kittens can be suggestive of infection with *Bartonella henselae* or *Toxoplasma gondii*. Children receiving cancer chemotherapy may have drug-induced hepatitis, and those who have experienced prolonged neutropenia may have fungal disease of the liver. Children with fulminant hepatitis are critically ill and initially may have persistent fever, protracted nausea and vomiting, severe abdominal pain, worsening jaundice, fluid retention with ascites, easy bruising, bleeding, and encephalopathy with seizures or coma. Patients with chronic hepatitis, on the other hand, often are clinically asymptomatic unless complications such as cirrhosis or chronic liver failure develop.

Physical Findings

Physical examination of a child with hepatitis should focus on the abdomen, liver, and spleen but also should include a careful evaluation for extrahepatic manifestations of systemic disease. Tender hepatomegaly, with or without ascites, scleral icterus, and jaundice, often is noted on physical examination of patients with acute hepatitis. Percussion over the right lower part of the thorax may produce right upper quadrant pain. Fever may or may not be present. Extrahepatic physical findings associated with the hepatotropic viruses, especially HAV, HBV, and HCV, include systemic vasculitis with rash or urticaria, polyarthralgia, and polyarthritis, similar to serum sickness or polyarteritis nodosa. A generalized papular rash, known as *Gianotti disease*, may accompany HBV infection, especially in young children. Rarely, a patient with acute viral hepatitis may exhibit Raynaud phenomenon, bullous lesions, or erythema nodosa on the extensor surfaces. Skin excoriations may be present if jaundice-associated pruritus is severe, and older children and adolescents may have vascular spiders or exacerbation of acne. A child who also has conjunctivitis, pneumonitis, and a maculopapular rash may have disseminated adenoviral disease. Generalized lymphadenopathy accompanied by pharyngitis and splenomegaly, in contrast, suggests systemic infection with CMV or EBV. Idiosyncratic reactions involving the liver may occur at any time; however, drug-related hypersensitivity hepatitis occurs 1 to 5 weeks after exposure to the agent and usually is accompanied by rash and fever on examination and evidence of nephritis, eosinophilia, and neutropenia. Neonates with acute fulminant hepatitis from disseminated HSV, enteroviruses, or adenoviruses may have fever or hypothermia, respiratory distress, abdominal distention, coagulopathy, myocarditis, seizure-like activity, or a sepsis-like syndrome. Physical examination of a child with fulminant hepatitis and liver failure may actually reveal a normal or small liver with new-onset irritability, confusion, lethargy, or personality changes. As hepatic failure ensues, the patient may become deeply jaundiced, icteric, and encephalopathic with hyperreflexia, decerebrate posturing, involuntary movements, and asterixis or may even become comatose. A distinctive sweet, fecal smell (also called *fetor hepaticus*) likely from ammonia, mercaptans, and ketones shunted from the liver to the lungs of a patient also may be appreciated by an astute observer. Physical examination of a child with chronic hepatitis, on the other hand, may reveal a normal or enlarged liver with splenomegaly. Splenomegaly is often the hallmark of portal hypertension related to chronic liver disease. If the child is obese, fatty infiltration of the liver should be considered as a cause of liver inflammation and dysfunction.

Laboratory Diagnosis

Laboratory evaluation of a child with acute hepatitis should include general blood and urine chemistries (complete blood cell count with differential, electrolytes, blood urea nitrogen, creatinine, urinalysis), tests of hepatic function (albumin, glucose, ammonia, coagulopathy panel, factors V and VII), and tests of hepatic inflammation/obstruction (serum aspartate aminotransferase and alanine aminotransferase [AST/ALT], alkaline phosphatase, γ-glutamyltranspeptidase, bilirubin). Serologic tests (i.e., HBsAg, HCV Ab), cultures, or detection assays (i.e., HCV RNA quantitative polymerase chain reaction [PCR]) for specific pathogens of interest according to the patient's screening laboratory results, history, or physical findings should also be pursued. Neonates with elevated aminotransferase levels should be tested for enterovirus and herpes simplex virus with viral cultures of secretions and virus-specific blood and spinal fluid PCR tests to assess for viremia and meningoencephalitis.

In many forms of viral hepatitis, the white blood cell count may be low, usually between 3000 and 4000/mm^3. Atypical lymphocytes also may be seen. Eosinophilia suggests a drug hypersensitivity reaction. If significant

leukocytosis is present, sepsis or fulminant hepatitis should be considered. A rising creatinine value may indicate development of hepatorenal syndrome. Urinalysis may reveal dark urine and the presence of urobilinogen. Hematuria with casts or other signs of nephritis in an older child may signify an autoimmune disorder or a drug-induced process as the cause of the hepatitis.

The hepatic aminotransferases, including AST and ALT, will be elevated in patients with acute hepatitis, often before the onset of clinical symptoms occurs. Most forms of acute hepatitis will be accompanied by elevations of 500 IU/mL or greater. A neonate with aminotransferase levels higher than 1000 IU/mL may have a potentially life-threatening infection with bacterial sepsis, HSV, enterovirus, or adenovirus. Similarly, older children with fulminant hepatitis or hepatic necrosis may have significantly elevated aminotransferase levels. These values may begin to fall after reaching a pinnacle; however, if the γ-glutamyltranspeptidase or conjugated bilirubin level continues to rise, this may indicate disease progression with massive hepatocyte necrosis rather than improvement. Prothrombin time, international normalized ratio, albumin, and glucose levels usually are normal in cases of uncomplicated acute viral hepatitis, but if coagulation factors become prolonged and hypoalbuminemia and hypoglycemia persist, fulminant hepatitis should be considered. Direct markers of hepatic synthetic function such as factors V and VII will also be low in the setting of liver failure. Serum bilirubin, both conjugated and unconjugated, may be elevated, but it is rarely higher than 4 mg/dL unless fulminant hepatitis with hepatic failure is present. Exceptions to this rule include patients with underlying hemolytic states such as glucose-6-dehydrogenase deficiency or sickle-cell disease; such patients may exhibit marked jaundice and high indirect hyperbilirubinemia even if the viral hepatitis otherwise is mild. Some patients will have low levels of nonspecific autoantibodies, such as an elevated homogeneous pattern of antinuclear antibodies, decreased complement levels, or false-positive Venereal Disease Research Laboratory (VDRL) test reactions. The erythrocyte sedimentation rate usually is normal or slightly increased in acute viral hepatitis.

Laboratory investigation to determine the specific cause of the patient's hepatitis includes an evaluation for the hepatotropic viruses. This often includes detection of serum hepatitis B surface antigen (HBsAg) and hepatitis B core antibody (HBcAb; IgM), serum hepatitis A virus antibody (HAV Ab; IgM), serum hepatitis C antibody (HCV Ab), serum hepatitis D antibody (HDV Ab) especially if the hepatitis is fulminant, and hepatitis E antibody (HEV Ab) if the travel history suggests exposure).[3,4] Both HBV and HCV have qualitative and quantitative PCR testing. Many of the nonhepatitis viruses may be identified by serologic tests that detect virus-specific IgM antibody or by fourfold rises in viral-specific IgG antibody. However, isolation of the specific viral agent in cell culture or detection of viral nucleic acid by PCR in blood, cerebrospinal fluid, body fluids such as saliva or stool, or liver tissue provides the most convincing evidence. Bacterial pathogens may be detected by culture for agents associated with granulomatous hepatitis, such as *Brucella* and *Mycobacterium*, or by a variety of culture, serology, or appropriate skin tests. In neonates, gram-negative enteric organisms (e.g., *Escherichia coli*) identified from the blood or urine are common causes of jaundice and hepatic dysfunction. Noninfectious causes of hepatitis should also be considered. Autoimmune hepatitis may be identified by persistent hypergammaglobulinemia and the presence of autoantibodies, such as F-actin and anti–liver-kidney-microsome antibodies (anti-LKM). Laboratory tests that evaluate for metabolic diseases include serum amino acids and urine-reducing substances and organic acids, sweat chloride testing for cystic fibrosis, α_1-antitrypsin levels and pi typing, serum ceruloplasmin and 24-hour urine collection for copper to rule out Wilson disease, and an iron panel for hemochromatosis. Acute hepatotoxicity from overdose of acetaminophen may be predicted from elevated acetaminophen levels. A urine or serum toxicology screen can assess for other toxic substances. Anatomic causes of hepatic dysfunction, such as biliary atresia in infants and hepatic tumors or steatosis in older children, usually require diagnostic imaging such as ultrasonography or liver biopsy for diagnosis.

INFECTIOUS CAUSES

Viruses

Hepatitis Viruses

Five hepatotropic viruses are known to cause infectious viral hepatitis in children: hepatitis A, B, C, D, and E (Table 47-1).

Hepatitis A Virus. HAV is a member of the Picornaviridae and formerly was known as enterovirus 72.[93] A small, nonenveloped RNA virus with icosahedral symmetry (Fig. 47-1), HAV is transmitted by the fecal-oral route, and transplacental transmission has been documented on rare occasion.[31,50] It is transmitted most commonly among young and school-aged children receiving care in group settings such as daycare, summer camp, schools, and institutions.[72] The incubation period generally is 30 days but ranges from 15 to 50 days. HAV infection in young children often is asymptomatic, and usually outbreaks in children are recognized first when symptoms occur in adult caretakers. Older children are more likely to have the classic symptoms of nausea, malaise, jaundice, and tender hepatomegaly. Rarely, HAV causes fulminant hepatitis. Acute infection with HAV is diagnosed serologically by detecting the presence of HAV IgM antibody in serum. No licensed, specific antiviral treatment is available. However, prevention may be accomplished by passive immunization with immune globulin or active immunization with licensed inactivated HAV vaccines.

Hepatitis B Virus. HBV, also known as *Dane particle* and *hepadnavirus type 1*, is a member of the Hepadnaviridae and is a DNA virus that is a 42-nm, nonenveloped spherical particle (Fig. 47-2).[93] There are eight known genotypes, of which A through D are the most predominant in the United States. It is transmitted through close

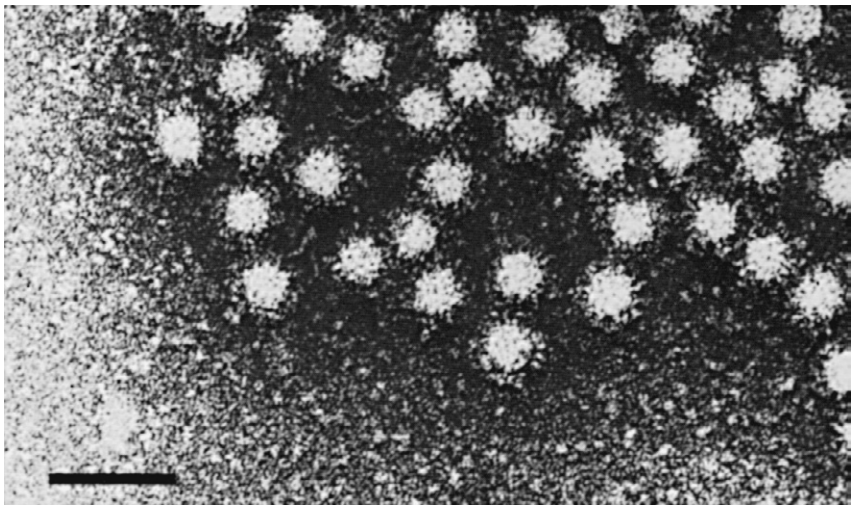

FIGURE 47-1 ■ A 27-nm hepatitis A virus (HAV) isolated from the stool filtrate of a patient with acute HAV infection. The HAV particles are aggregated by convalescent serum containing anti-HAV antibodies. The *line* represents 100 nm. (Courtesy of Dr. Jules Dienstag, taken at the Laboratory of Infectious Diseases, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Department of Health, Education, and Welfare, Bethesda, MD.)

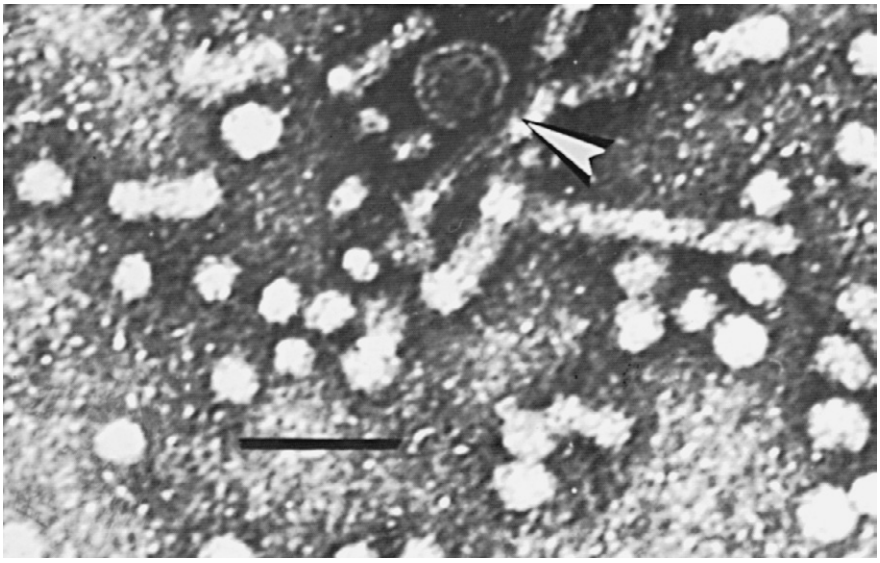

FIGURE 47-2 ■ Electron micrograph of hepatitis B virus particles. Most particles are 20 to 25 nm in diameter and consist of both spheres and tubules. A larger, 42-nm Dane particle also is present *(arrowhead)*. Hepatitis B surface antigen determinants are present on the surface of all three forms.

contact with blood or blood-contaminated secretions, objects, or products.[50] It also has been transmitted by organ transplantation, intravenous drug use, and sexual contact. The incubation period is prolonged, usually 90 days, with ranges of 45 to 160 days reported. Neonates may acquire HBV vertically from mothers who are actively infected with HBV, especially if the mothers also are positive for hepatitis B e antigen (HBeAg). Whereas neonates and toddlers rarely are symptomatic, older children and adults may have mild to moderate symptoms of acute hepatitis or progress to fulminant or fatal disease. HBV also is a common cause of chronic hepatitis in children. Chronic hepatitis will develop in approximately 10 percent of older children and adults infected with HBV; the figure rises to approximately 30 percent if the infection occurs during infancy or early childhood and reaches a striking 90 to 95 percent in infants born to infected mothers who are HBeAg positive. Acute hepatitis B is diagnosed serologically by the presence of HBsAg and HBcAb, which can identify infected patients in the window period. HBV DNA also may be detected and quantified in serum by PCR during acute hepatitis. Individuals with HBeAg in their serum are highly infectious. Diagnosis of chronic hepatitis B requires a combination of persistent clinical symptoms and laboratory abnormalities, persistence of specific serologic markers such as HBsAg over a period of at least 6 months, and histopathologic characteristics on liver biopsy. Primary hepatocellular carcinoma also is a long-term complication of infection with HBV. Successful resolution of infection with HBV is marked serologically by the presence of antibody to HBsAg, known as HBsAb in the nomenclature. For patients with chronic hepatitis B, the decision to treat is largely based on ALT level, HBV viral load, and liver histology.[68] First-line therapy in children with compensated disease remains interferon-α.[77] Three nucleos(t)ide analogs are also age approved for use. Of these, lamivudine and adefovir can be used in younger children, although due to a high rate of resistance even after one year of treatment, these are not recommended; however, entecavir has been shown to have higher potency as well as lower resistance rates, and while it has a product indication in children older than 16 years, it is not yet FDA approved.[22,77,154] Tenofovir is now a first-line therapy in adults but is currently limited to use as therapy for HIV infection in children.[163] Both entecavir and tenofovir are awaiting results of phase III trials in children and will likely soon be first-line options for children. Evidence also suggests that therapeutic response to these medications may vary by HBV genotype.[38] Liver transplantation has been attempted in patients with end-stage HBV-associated cirrhosis, with variable results. Prevention is achieved by passive immunization with hepatitis B immune globulin (HBIG) in the delivery room and active immunization with licensed recombinant vaccines.[57] Pregnant women with chronic hepatitis B should have their HBV viral load and HBeAg status determined to assess their risk for vertical transmission. All infants born to infected women should receive hepatitis B immunoglobulin (HBIG) at delivery and a vaccination within 12 hours of birth. However, if there is high risk for transmission, lamivudine or telbivudine may be administered to the mother during pregnancy.[60,118,119]

Hepatitis C Virus. HCV is a member of the Flaviviridae. It is a small RNA virus that is highly heterogeneous. Eleven genotypes with several distinct subtypes have been identified throughout the world and appear to have a variable effect on the development of clinical disease and response to antiviral therapy. It is transmitted most commonly to children and adolescents who have been exposed to blood products, clotting factor concentrates before 1987, hemodialysis, organ transplantation, intravenous drug use, cocaine snorting, or tattoos and piercing procedures performed at parlors that do not practice sterile technique. Perinatal transmission from an HCV-seropositive mother to her infant also occurs at an estimated risk of 5 percent, especially if the mother is HCV RNA positive at delivery.[109,114] Infection with HCV usually does not cause acute hepatitis; however, chronic hepatitis develops in more than 50 percent of children infected with HCV.[28] In adults, cirrhosis, end-stage liver

failure, and hepatocellular carcinoma also may develop. Infection with HCV is diagnosed serologically by detecting the presence of HCV antibody and confirming with HCV RNA quantification by PCR.[83] Use of peginterferon-α2b (PegIntron) plus ribavirin is considered first-line therapy in children. Achieving a sustained virologic response, defined as being HCV RNA negative 6 months after discontinuation of treatment, is the standard of care. The rates of achieving a sustained virologic response with treatment in children with genotypes 2 and 3 are much higher (75% to 80%) than in children with genotype 1 (35% to 40%).[144,160] Treatment response, and even spontaneous clearance without treatment, seem to be strongly influenced by a genetic polymorphism near the *IL28B* gene.[54,141] Directly acting antiviral agents, such as the protease inhibitors telaprevir and boceprevir, have significantly increased sustained virologic response rates (by nearly twofold) in adults when used in combination with peginterferon-α2b plus ribavirin and were approved in 2011.[75,128] Pediatric studies will soon be underway. Liver transplantation may be performed in patients with end-stage liver disease. Currently, no biologic products or vaccines are licensed for prevention of infection with HCV. The heterogeneity of HCV has hindered the development of such products because vaccine antigens from multiple serotypes will probably be necessary for global protection.

Hepatitis D Virus. HDV, also known as the *delta agent*, *delta virus*, *helper virus*, and *defective virus*, is a small, 37-nm RNA virus that requires the presence of HBV, especially HBsAg, to replicate.[127] HDV can coinfect a patient simultaneously or subsequent to infection with HBV. Like HBV, HDV is acquired by exposure to blood products or clotting factors, intravenous drug use, or sexual contact. It also may be transmitted by liver transplantation, and vertical transmission has been reported. Infection with HDV occurs more commonly in Europe, South America, Africa, and the Middle East and appears to be less common in the United States. The incubation period after superinfection occurs is 1 to 2 months, but it is similar to that for HBV (90 days) if coinfection occurs simultaneously. Coinfection with HDV is associated with more severe disease or progression to fulminant hepatitis in HBV-infected patients.[127] Laboratory diagnosis includes detection of HDV antibody (IgG, IgM) and HDV RNA by PCR, although this is not commercially available. Treatment with peginterferon-α2b results in sustained HDV clearance in about one fourth of patients.[71,156] Because HDV cannot be transmitted to or infect humans without HBV, prevention of HBV infection by vaccination prevents the acquisition of HDV infection. HDV coinfection of individuals already infected with HBV, however, cannot be prevented by any licensed biologic product or vaccine.

Hepatitis E Virus. HEV is a small RNA virus that is transmitted by the fecal-oral route.[12,120,129,134] HEV infection in U.S. residents is a rare occurrence, but it may be a common cause of acute, self-limited viral hepatitis in developing countries and has been linked to outbreaks associated with contaminated water supplies.[52,101,108] The incubation period is an average of 6 to 7 weeks.[2] HEV appears to cause a mild to moderate, acute hepatitis, especially in adults, and may have a high case-fatality rate in pregnant women. Chronic hepatitis is rare but has been seen in immunosuppressed patients.[2] Laboratory diagnosis is established by detection of IgG and IgM antibody to HEV in serum or detection of HEV RNA by PCR in serum or feces performed in reference laboratories or at the Centers for Disease Control and Prevention (CDC). No antiviral agent is licensed for HEV, although peginterferon-α2b has been shown to achieve a sustained virologic response. Two candidate vaccines have achieved 95 to 100 percent protective efficacy, but neither has been licensed for marketing.[2]

Herpesviruses

Herpesviruses are large DNA viruses with icosahedral symmetry and a glycoprotein envelope, and they share the biologic properties of latency and reactivation. Infections with this family of viruses, the Herpesviridae, may be primary or recurrent. All the human herpesviruses (HHVs) and one of the primate herpesviruses (herpes B virus) can cause acute hepatitis during the course of a systemic illness, but primary hepatitis with these viral agents is an unusual event.[48]

Herpes Simplex Virus. HSV-1 and HSV-2 most often cause mucocutaneous vesicles or ulcers, and dissemination usually occurs during periods of relative immune compromise, such as pregnancy, the neonatal period, malnutrition, congenital or acquired immunodeficiency syndromes, or organ transplantation. Transient, subclinical hepatitis may occur during acute mucocutaneous HSV disease, but fulminant hepatitis with hepatic necrosis rarely has been documented in a normal host.[44,51,79,98] A special exception to this observation is HSV-associated primary hepatic necrosis and disseminated HSV disease in pregnant women.[51] Most cases occur during the late second or early third trimester, and most, but not all, cases are associated with primary infection with HSV-2.[159,162] Obvious skin lesions may not be present. This disease is associated with high mortality rates in both the mother and infant. Neonates, both term and preterm, are at risk for the development of neonatal HSV hepatitis as part of a disseminated HSV disease that includes viral sepsis–like syndrome, coagulopathy, abdominal distention with hepatomegaly and ascites, pneumonitis with respiratory distress, and meningoencephalitis.[19,74] Skin lesions often are absent in this form of HSV disease. Neonatal HSV hepatitis develops most often in the child's first 2 weeks of life, and aminotransferase levels may initially be slightly elevated, then rise to be more than a thousand times higher than normal as disease progresses. Recipients of solid organ, bone marrow, and stem cell transplants may have HSV infection with dissemination within the first 3 weeks after undergoing transplantation, most often as a result of reactivation.[49] Patients with hepatitis secondary to HSV infection may be shedding HSV from a mucocutaneous source or may be viremic with virus detected in the blood by DNA PCR. Some patients may require analysis of ascites fluid or liver

biopsy for confirmation. Acyclovir therapy is recommended for HSV-associated hepatitis, and post-transplant prophylaxis is very effective in preventing post-transplant HSV disease.[159] Children with HSV fulminant hepatitis have significantly better survival rates than adults before and after liver transplantation.[36,102]

Varicella-Zoster Virus. Varicella-zoster virus also causes mucocutaneous vesicles in both immunocompetent and immunocompromised hosts. Primary infection is known as *varicella* (also chickenpox) and is associated with primary and secondary viremias that often seed the visceral organs. Approximately a fourth of healthy children experiencing varicella will have silent hepatitis with aminotransferase levels at least twice normal.[47,108,126] Fulminant hepatitis with varicella is rare and generally is seen in immunocompromised hosts.[6,105,121,147] Patients have severe abdominal pain with little nausea or vomiting, skin lesions may or may not be present, and aminotransferase levels may be more than a thousand times higher than normal.[104,140,143] Zoster in a normal host is not associated with fulminant hepatitis, but immunocompromised hosts may experience disseminated zoster with hepatitis and hepatic necrosis.[46] The diagnosis often is based on clinical findings, but viral culture or direct fluorescent antibody testing of cutaneous lesions, if present, or viral culture or viral DNA detection by PCR of blood and liver biopsy also may help establish the diagnosis. Treatment with acyclovir is recommended. Varicella may be prevented or attenuated by passive immunization with varicella-zoster immune globulin (VZIG) or intravenous immunoglobulin (IVIG) or by active immunization with a licensed live virus vaccine.[20,29]

Cytomegalovirus. CMV infection usually is asymptomatic or "silent." However, CMV may cause gastroenteritis, pneumonitis, or a mononucleosis-like syndrome that consists of fever, lymphadenopathy, and atypical lymphocytosis. Hepatitis occurs as part of these syndromes but often is silent or mild and rarely is accompanied by jaundice.[81,97] Granulomatous hepatitis also may be associated with CMV.[32] Infants born congenitally infected with CMV frequently have hepatosplenomegaly, elevated aminotransferase levels, and conjugated hyperbilirubinemia.[32,33,153] The hepatitis that neonates and infants experience is self-limited and generally resolves within the first few months of life. If hepatitis with cholestasis persists, other diseases such as extrahepatic biliary atresia should be considered. Solid organ and marrow transplant recipients and patients with acquired immunodeficiency syndrome (AIDS) and other immunodeficiency states may experience persistent fever, malaise, leukopenia, and hepatitis caused by primary or recurrent infection with CMV. Severe liver disease can occur in transplant recipients and may be associated with graft-versus-host disease or graft rejection.[41,42] CMV-associated hepatitis may be diagnosed clinically and supported by virologic evidence of positive cultures, CMV viremia (or a viremia surrogate marker such as CMV antigenemia or CMV DNAemia), or demonstration of involvement of the end-organ by liver biopsy.[40,111] Treatment with ganciclovir, valganciclovir, foscarnet, or cidofovir appears to be beneficial in immunocompromised hosts, and prophylaxis or preemptive therapy with antiviral agents or CMV hyperimmune globulin may prevent the development of severe CMV disease in transplant recipients.[40,43,52]

Epstein-Barr Virus. EBV infection usually is asymptomatic or "silent," but it may cause a mononucleosis-like syndrome with mild hepatitis. However, in rare patients with a genetic X-linked predisposition, a severe, often fatal lymphoproliferative syndrome with prominent liver involvement may develop. Transplant recipients also may be susceptible to post-transplant lymphoproliferative disease (PTLD), in which the liver may be involved.[9,26,137] In addition, patients with tumors associated with EBV, such as lymphoma, may have hepatic involvement. The diagnosis of mononucleosis usually is clinical and supported by a positive heterophile or "Monospot" test or by specific EBV serologic tests such as detection of IgM antibody to viral capsid antigen (VCA).[13] The immune response to EBV in immunocompromised hosts may be unusual, and the diagnosis of PTLD generally is suspected by an exponential increase in EBV DNA genome copies in peripheral blood, generalized adenopathy, visualization by positron emission tomography, and the presence of histopathologic features on biopsy. Treatment options for PTLD include reducing immunosuppression, rituximab (anti-CD20 monoclonal antibody), adoptive immunotherapy, interferon-α, and anti–interleukin-6 antibody.[30,58,62,116,142] Antiviral agents such as acyclovir or foscarnet should be used only as an adjunct therapy because they are less effective in the latent phase of PTLD.[62]

Human Herpesviruses 6, 7, and 8. These viruses may involve the liver, especially in immunocompromised patients.[48] Infection with HHV-6 in recipients of liver transplants is usually a result of reactivation and has been associated with acute rejection, portal lymphocyte infiltration, and graft dysfunction. Even though HHV-6 commonly can be detected in blood and tissue, high viral loads have been associated with decreased graft survival.[125] Normal hosts with primary HHV-6 infection may have a silent hepatitis with mild elevation of aminotransferase levels. Rarely, severe disseminated disease with fulminant hepatitis has been linked to HHV-6 and HHV-7.[3,10,63,94] HHV-8 (also known as *Kaposi sarcoma virus*) causes a complex neoplasm involving the skin, mucous membranes, and internal organs, most often in severely immunocompromised patients. Although rare, it has been reported in human immunodeficiency virus (HIV)-infected children with advanced AIDS. Recipients of solid organ transplants may be infected with HHV-8. The liver is a common site of visceral disease caused by HHV-8, which most often is associated with tumors rather than hepatitis.[27] Diagnosing infection with HHV-6, HHV-7, or HHV-8 is difficult because of the ubiquity of these viruses and their viral DNA in humans, but the diagnosis is supported by serologic evidence and by detection of viral DNA in blood, in secretions, or, more specifically, in tissue.[117] No specific licensed antiviral therapy is available, but these viruses may be inhibited by ganciclovir, foscarnet, and cidofovir. Response also may be noted after withdrawal or reduction of immunosuppression. Chemotherapy may be indicated in some cases of HHV-8.

Herpes B Virus. Also known as *herpesvirus simiae* or *cercopithecine herpesvirus 1*, herpes B virus is an α-herpesvirus of monkeys that causes severe disease in humans.[158] It can be transmitted from Asian monkeys, such as rhesus and cynomolgus monkeys, to humans through bites or contact with mucous membrane secretions from infected monkeys. The human disease associated with herpes B virus involves skin vesicles at the portal of entry, regional lymphadenitis, and hemorrhagic encephalitis. The virus also may disseminate to the liver and lungs and produce hemorrhagic necrosis, with a high mortality rate. The diagnosis is made by isolation of virus or detection of viral DNA by PCR in specialized reference laboratories, and the virus is inhibited by acyclovir and ganciclovir.

Adenoviruses

Adenoviruses are small DNA viruses that are members of the viral family Adenoviridae. They usually are respiratory or enteric pathogens, but they can cause disseminated disease with hepatitis and hepatic necrosis in both immunocompetent and immunocompromised hosts and neonates.[67,96,113] Patients often have fever, malaise or lethargy, conjunctivitis, pharyngitis, cough, respiratory distress, vomiting and diarrhea, and a viral sepsis–like syndrome. Hepatitis is marked by hepatomegaly and by elevated aminotransferases and bilirubin. A specific viral diagnosis is made by isolation of adenovirus or detection of adenoviral DNA by PCR from respiratory secretions, blood, stool, or tissue. Adenovirus serotype 5 generally is associated with severe hepatitis, followed in frequency by types 1 and 2.[106] Viral surveillance cultures, blood DNA PCR testing, and virus serotyping and genotyping in immunocompromised patients, such as bone marrow and stem cell transplant recipients and liver transplant recipients at high risk for acquiring severe or fatal adenovirus-associated disease, may allow early intervention before severe, disseminated disease develops.[21,57,96] No licensed antiviral therapy is available, but the virus is inhibited to some extent by antiviral agents such as ribavirin and ganciclovir, and case reports suggest a potential clinical benefit in some patients with severe adenoviral hepatitis treated with cidofovir, an antiviral agent with broad-spectrum activity against many DNA viruses.[18,86]

Erythroviruses—Human Parvovirus B19

Erythroviruses (e.g., human parvovirus B19) are small DNA viruses. They are members of the family Parvoviridae and are responsible for a variety of illnesses, including fifth disease (i.e., erythema infectiosum), arthritis, and anemia. Liver involvement, often severe, may be seen in intrauterine infection with hydrops fetalis.[5,95] Fulminant liver failure with massive hepatic necrosis also has been reported in patients with aplastic anemia.[82] Pediatric patients with fulminant liver failure from the hepatotropic viruses have more severe disease and high mortality rates when coinfected with human parvovirus B19.[35] Persistent infection is seen in immunocompromised hosts. Parvovirus infection can be diagnosed by detection of virus-specific IgM antibodies or detection of viral DNA in blood, serum/plasma, bone marrow, secretions, urine, or tissue. No specific antiviral therapy is available, but immunocompromised patients with chronic infection may benefit from receiving IVIG. Severe fetal hydrops usually requires in utero and neonatal blood transfusions for anemia.

Enteroviruses

Enteroviruses are small RNA viruses and members of the Picornaviridae, along with polioviruses and rhinoviruses. The nonpolio enteroviruses often are associated with mild respiratory or gastrointestinal illnesses, myocarditis, or aseptic meningitis, most often occurring in late summer or early fall. Significant hepatic necrosis can occur in neonates with disseminated disease, particularly with serotype echovirus 11. It often is accompanied by hepatomegaly, thrombocytopenia, viral sepsis syndrome, aseptic meningoencephalitis, myocarditis, and elevated aminotransferase and serum bilirubin levels.[99-101] Coxsackievirus B and echoviruses 9 and 30 also are associated with fatal disease. Enteroviruses may be transmitted to neonates perinatally from the mother or through contact with ill family members. Health care–associated nursery outbreaks with enteroviruses also have been reported.[100] The diagnosis is established by isolation of the virus or detection of viral RNA by PCR in throat, stool, urine, blood, cerebrospinal fluid, or tissue samples. Treatment is supportive; however, case reports suggest that IVIG and pleconaril may have some clinical benefit in severely ill neonates.[7,24,76,133]

Measles Virus

Measles virus is an RNA virus that is a member of the Paramyxoviridae, along with parainfluenza viruses, respiratory syncytial virus, metapneumovirus, and mumps virus. Of all the paramyxoviruses, measles virus is associated most often with hepatitis. Ten to 20 percent of children with measles will have subclinical hepatitis, although severe disease of the liver, lungs, and brain may occur in immunocompromised patients.[53,110,145] Rare reports of severe giant-cell hepatitis, often leading to liver failure, have implicated paramyxoviruses of undetermined type.[124] Measles and other paramyxoviruses may be identified by detection of virus-specific IgM antibody in serum and by isolation of virus or detection of RNA by PCR in secretions, blood, or tissue. No specific antiviral therapy is licensed for measles virus; however, ribavirin, a broad-spectrum antiviral agent, may have some activity against the virus. Prevention is achieved by vaccination with the live measles vaccine or by postexposure administration of immunoglobulin or IVIG.

Rubella Virus

Rubella virus is a member of the Togaviridae of RNA viruses. Clinical disease associated with infection by rubella virus generally is mild, but as many as 10 percent of children with rubella may have subclinical hepatitis with transient elevation of aminotransferase levels.[150] Congenital rubella syndrome caused by intrauterine infection with rubella virus, however, is associated with significant liver involvement, and hepatomegaly with

jaundice is noted at birth.[39,103,149] Congenital rubella syndrome also is associated with intrauterine growth retardation, cataracts, congenital heart disease, thrombocytopenia, purpura, and hearing loss.[80] Because isolating the virus is technically challenging, the diagnosis of rubella most often is made serologically by detection of virus-specific IgM antibody or by detection of viral RNA by PCR in reference laboratories. No specific antiviral therapy is available. Rubella can be prevented, however, by vaccination with the live rubella virus vaccine.

Hemorrhagic Fever Viruses

The hemorrhagic fever viruses are a diverse group of RNA viruses from a variety of different virus families. They include arenaviruses such as Lassa fever virus, bunyaviruses such as hantavirus, filoviruses such as Marburg and Ebola, and flaviviruses such as yellow fever virus and dengue. Hemorrhagic fever is characterized by fever, malaise, or lethargy, headache, retro-orbital pain, myalgia, conjunctivitis, rash, and intravascular coagulation with hemorrhage.[37] Liver involvement with these viruses is a very common event, and elevation of aminotransferase levels to 500 IU/mL occurs in almost every patient, with a thousand times the normal range seen in patients who are severely ill.[37] Jaundice is a significant component of yellow fever.[73] The diagnosis is established by serologic means or by detection of the viral agent with electron microscopy or PCR techniques, which in most cases should be attempted only in biosafety level IV reference laboratories. Treatment of most hemorrhagic fevers is supportive; however, intravenous ribavirin reduces the mortality rate associated with Lassa fever and also may be of benefit to patients with hemorrhagic fever caused by other arenaviruses.[88,92]

Bacteria

Nonviral acute hepatitis can be caused by bacterial illnesses (see Table 47-1).[112] Sepsis with gram-positive organisms, especially pneumococci, or with gram-negative organisms, particularly gram-negative enteric bacteria, can produce hepatic dysfunction, primarily from the cholestatic effects induced by bacterial endotoxins.[112,166] In this form of hepatic dysfunction, the patient will appear jaundiced with mild hepatomegaly and conjugated bilirubin levels will be elevated out of proportion to the modest elevation in aminotransferase or alkaline phosphatase levels. Neonates also may have jaundice secondary to urinary tract infection with gram-negative enteric organisms. The diagnosis is made by isolating the offending bacteria from blood, urine, or other usually sterile site. Treatment involves specific antimicrobial therapy.

Other bacterial diseases may cause chronic or granulomatous hepatitis, including actinomycosis, brucellosis, listeriosis, nocardiosis, bartonellosis (cat-scratch disease), and tuberculosis.[8,115] Diseases caused by atypical mycobacteria, especially *Mycobacterium avium-intracellulare* complex (MAC complex) or *Mycobacterium mucogenicum* may be seen, particularly in patients with congenital or acquired immunodeficiency states.[55] Rarely, disseminated disease with hepatitis can occur as a complication of vaccination with bacille Calmette-Guérin (BCG) in children or, in adults, as a complication of bladder irrigation for bladder carcinoma.[8,56,85] Bacterial toxins, such as the emetic toxin of *Bacillus cereus*, also have been linked to fulminant hepatic failure in some patients.[89] A diagnosis of hepatitis caused by these unusual or indolent bacterial pathogens usually is accomplished by isolating the organism from blood or the affected organ. The diagnosis may be supported by positive skin test results in the case of tuberculosis or atypical mycobacterial disease, serologically by elevated titers to *Bartonella quintana* or *Bartonella henselae*, and by positive imaging studies that show hepatic microabscesses, as in the case of hepatic involvement with cat-scratch disease. Antimicrobial therapy is guided by the susceptibility of the offending pathogen.

Spirochetes

Acute infection with *T. pallidum*, the agent of primary or early secondary syphilis in adolescents or adults, may cause acute or granulomatous hepatitis with serum aminotransferase levels up to 5 to 10 times normal.[84] Jaundice rarely develops, but a chancre of primary disease or a rash of secondary disease often is present. Congenital syphilis also is associated commonly with hepatosplenomegaly in the neonate, along with elevated aminotransferase and bilirubin levels. Other clinical manifestations of congenital syphilis include petechiae or purpura, osteitis, and meningitis. Laboratory diagnosis is confirmed by reactive VDRL and positive fluorescent treponemal antibody tests.[66] Treatment with penicillin is recommended.

Leptospirosis, or infection with the pathogenic bacterium *Leptospira interrogans*, can cause acute hepatitis.[64] Leptospirosis usually is an abrupt, anicteric, flulike illness, but approximately 10 percent of patients will have an icteric or septicemic syndrome with a biphasic clinical course. Patients with the icteric or severe form will exhibit jaundice, hepatomegaly, and characteristic conjunctival injection. Usually, levels of serum bilirubin are elevated out of proportion to the more modest elevations in serum aminotransferases, suggesting a defect in excretion of bilirubin rather than direct hepatic necrosis as the pathogenesis of the jaundice. Meningitis, renal failure, and even liver failure may occur in some patients. The diagnosis should be considered in older children and adolescents with a history of exposure to wild and domestic mammals, especially dogs, rats, and livestock, which may excrete *Leptospira* organisms in their urine, or with a history of exposure to contaminated water in ditches, lakes, or streams. The diagnosis is established by isolating the organisms on special media during the acute phase of illness. Serologic and PCR tests also are available in reference laboratories. Treatment with penicillin or doxycycline is recommended.

Rickettsiae

The rickettsial organism *Coxiella burnetii* causes Q fever, both the acute and chronic forms, in which hepatitis is a prominent feature along with persistent fever, malaise,

rash, weight loss, and pneumonitis.[15] Clinical jaundice is a rare finding, and most often the hepatitis is subclinical. A history of exposure to mammals or birds suggests the diagnosis, which can be confirmed serologically by reference clinical laboratories. Treatment with antibiotics, usually doxycycline, is recommended.

Parasites and Fungi

A variety of parasites may invade the liver and occasionally cause hepatic dysfunction or disease.[112,164] Such parasites include *Plasmodium* spp. (malaria), *Entamoeba histolytica* (liver abscess), *T. gondii* (toxoplasmosis), and *Toxocara canis* (visceral larval migrans). *Ascaris lumbricoides* (roundworms) may invade the common bile duct and cause acute obstructive jaundice.

Fungi also may invade the liver, usually with only minimal elevation of aminotransferase levels and rarely causing jaundice or elevated levels of bilirubin. Patients with a compromised immune system may have hepatic abscesses with *Candida* spp. or abscesses or necrotic lesions with *Aspergillus* spp., as well as other unusual fungal species. Both immunocompromised and normal hosts may have liver involvement with *Histoplasma capsulatum* or *Cryptococcus neoformans*.[112]

NONINFECTIOUS CAUSES

An important noninfectious cause of acute hepatitis is drug-related hepatitis (see Table 47-1).[107,161,165] It can range in severity from mild, with subclinical elevation of aminotransferase levels, to fulminant hepatic failure.[78] A careful history of ingestion of prescription or over-the-counter medications, as well as exposure to toxins or herbal remedies, should be elicited. Although almost any drug can cause acute hepatitis, the most common agents associated with hepatitis in children include acetylsalicylic acid (i.e., aspirin), acetaminophen, isoniazid, rifampin, phenytoin, valproic acid, phenobarbital, β-lactam antibiotics (e.g., oxacillin, nafcillin, and third-generation cephalosporins), sulfa drugs, and antifungal agents such as ketoconazole and fluconazole. Many of the above medications, including allopurinol and carbamazepine, have been implicated in the potentially life-threatening DRESS syndrome (Drug Reaction with Eosinophilia and Systemic Symptoms). The majority of patients with DRESS syndrome have hepatic involvement, and the treatment is withdrawal of the offending agent and corticosteroid therapy.[17] The anesthetic drug halothane also can cause acute hepatitis with jaundice.[132] Gold and other metals used to treat arthritis, carbon tetrachloride, and ingestion of *Amanita* mushroom, can all lead to liver injury. In addition, chronic hepatitis can develop in children, especially premature infants, who receive prolonged total parenteral nutrition (for 2 weeks or more).

Anoxic liver injury also can resemble acute viral hepatitis. It occurs in critically ill children after a period of hypotension, heart failure, or cardiopulmonary arrest. A history of such an inciting event supports the diagnosis. Anoxic liver injury is characterized by an abrupt onset of markedly elevated levels of aminotransferases, often hundreds of times higher than normal, without jaundice, and rapid recovery of enzyme levels to normal or nearly normal after the event has resolved.[65]

Other diseases such as Kawasaki syndrome and toxic shock syndrome, which have been linked to or associated with infectious pathogens, may have hepatitis as part of their manifestation. Similarly, Reye syndrome, characterized by hepatomegaly with fatty infiltration of the liver and often fatal encephalopathy, may occur after a viral syndrome such as varicella or influenza.

Metabolic disorders may manifest as hepatitis, especially in infants. Such disorders include cystic fibrosis, α_1-antitrypsin deficiency, galactosemia, hereditary fructose intolerance, glycogen storage disease, urea cycle deficiencies, organic acidemias, tyrosinemia, and lipid storage diseases such as Gaucher and Niemann-Pick disease.[122,151] Of note, cystic fibrosis in neonates may be associated with cholestatic jaundice in the absence of pulmonary disease, similar to biliary atresia.[146] Disorders of metal metabolism, such as Wilson disease or hereditary hemochromatosis, may cause acute, chronic, or even fulminant hepatitis in older children.[123,138] A distinct disorder, neonatal hemochromatosis, is hypothesized to be an alloimmune-mediated (maternal) hepatitis that often manifests as severe liver injury within hours of birth and notable coagulopathy.[157] In addition, patients with congenital disorders of bilirubin metabolism or transport may become jaundiced without significant elevation of aminotransferase levels, especially during an intercurrent viral illness. Of these, Rotor and Dubin-Johnson syndromes predominantly cause a conjugated hyperbilirubinemia and do not lead to hepatic injury.[148] Gilbert syndrome and Crigler-Najjar type 1 and 2 are on the same spectrum of disease causing unconjugated hyperbilirubinemia, with the complete loss of bilirubin glucuronidation being fatal.[148] Sickle-cell crisis also may manifest as hepatitis.[139]

Tumors of the liver such as hepatoblastoma and hemangioendothelioma and infiltrative diseases such as lymphoma, leukemia, and hemophagocytic lymphohistiocytosis syndrome may have hepatitis or hepatic failure as part of the initial manifestation.[61,90] Another multisystem disorder that may produce chronic granulomatous hepatitis is sarcoidosis.[34]

Anatomic causes of hepatic dysfunction in infants include extrahepatic biliary atresia, which usually develops in the first 2 months of life.[91,153]

Autoimmune hepatitis or other autoimmune disorders with liver involvement also may cause acute or chronic hepatitis, especially in older children and adolescents.[155] These disorders often are associated with rash, arthritis, inflammatory bowel disease, thyroiditis, malaise, and persistent fever. Autoimmune hepatitis may respond to corticosteroids or other immunosuppressive agents.

Hepatic steatosis (fatty infiltration) is becoming more and more common in obese children, especially if insulin resistant. These children may have enlarged or tender livers on examination, elevated aminotransferase levels in serum, abnormal imaging studies showing fatty infiltrates of the liver, and liver biopsies that show inflammation, fibrosis, and even cirrhosis in some cases. Treatment

currently includes diet and lifestyle changes with weight loss and exercise.

One specific pediatric population—children with biliary atresia and a hepatic portoenterostomy (HPE)—is particularly susceptible to cholangitis and its sequelae. This population and other patient groups at high risk for developing infectious cholangitis, such as patients with immunodeficiency states, congenital or acquired bile duct abnormalities, or liver transplants, are highlighted in this chapter. Biliary tract obstruction secondary to gallstone disease is discussed in the section on cholecystitis.

ETIOLOGY AND PATHOGENESIS

The central mechanism leading to biliary tract infection is obstruction of normal bile flow. Bile typically is sterile, owing to mechanical flushing with normal bile flow, the anatomic gate of the choledochal sphincter, bacteriostatic properties of bile, and biliary IgA.[34,144] When obstruction and stagnation occur, bacteria gain access either by ascending from the gut or via hematogenous spread. The exact route of bacterial invasion and spreading remains controversial. Ascent may occur from the duodenum, most commonly in the presence of abnormal function of the sphincter of Oddi. In addition, bacterial invasion may occur hematogenously via increased gut translocation across the intestine into the portal circulation,[250] followed by flow across the gallbladder wall.[59] Although the exact mechanism has not been firmly established, the consensus is that transient episodes of bactibilia combined with biliary obstruction may lead to higher concentrations of bacteria in the biliary tract. As biliary pressure increases, bacteria likely migrate from the bile ducts into lymphatic and blood vessels, resulting in bacteremia and clinical signs and symptoms of cholangitis.[34,111] Iatrogenic introduction of bacteria into the biliary tract can occur during endoscopic retrograde cholangiopancreatography (ERCP) or with indwelling stents.[144]

In adults, cholangitis typically occurs in the presence of biliary tract obstruction secondary to impaction of gallstones in the common bile duct, leading to bile stasis and secondary infection. In approximately 85 percent of cases of cholangitis in adults, evidence of a common bile duct stone is present.[18] In adults with documented gallstones in the common bile duct (choledocholithiasis), the incidence of positive bile cultures is 30 to 99 percent.[146,153,231] Other potential causes of biliary obstruction in adults, possibly leading to a more chronic or recurrent presentation, include neoplasm of the biliary tree or head of the pancreas, other intrinsic or extrinsic strictures, parasitic disease, inflammatory conditions (e.g., primary biliary cirrhosis, primary sclerosing cholangitis [PSC]), and congenital bile duct anomalies. More recently, with improved imaging modalities and a better understanding of the pathogenesis of biliary lithiasis, it has become accepted that biliary sludge or microcalculi may be at the root of nonobstructive cholangitis and recurrent biliary infections.

In children, acute cholangitis occurs most frequently in patients with biliary atresia who have undergone HPE surgery, also known as a *Kasai operation*. HPE provides a permissive setup for cholangitis: poor bile flow combined with damaged intrahepatic bile ducts and obligate bacterial colonization with enteric flora in the intestinal conduit.[105,135,150,217] In this setting, cholangitis is thought to arise from reflux of jejunal flora through the HPE (Roux-en-Y loop), directly contiguous with the hepatic porta. Incidence is between 40 to 93 percent of patients and tends to occur more frequently within the first year after surgery.[48,66,217] Decreased biliary and duodenal motility generally is accepted as being associated with a higher incidence of cholangitis,[63,252] but most predictors and exacerbants for the development of cholangitis remain unknown.

Microbiologic evidence of biliary tract infection ideally should involve at least 10^5 organisms per milliliter of bile.[59] The frequencies of specific organisms found in adult and pediatric studies are summarized in Table 48-1.[19,28,127,149,206] *Escherichia coli*, *Klebsiella pneumoniae*, *Enterobacter* spp. and *Enterococcus* spp. are most commonly isolated from infected bile. Many cases of cholangitis are polymicrobial. Anaerobes, such as *Bacteroides fragilis* and *Clostridium perfringens*, also may play a significant role and have been identified in 40 percent of biliary tract infections.[29] Specifically, the latter organism has been implicated in acute emphysematous cholecystitis. Despite these findings in bile, many patients with cholangitis have

TABLE 48-2 **Diagnostic Criteria for Acute Cholangitis**

Definitive Diagnosis	Charcot Triad, 1877	Tokyo Guidelines, 2006
Clinical signs of infection and finding of purulent bile by:	Fever	Two of three Charcot triad criteria plus:
Endoscopic retrograde cholangiopancreatography	Right upper quadrant pain	Evidence of inflammatory response
Surgery	Jaundice	Abnormal white blood cell count
Percutaneous puncture	**Reynold Pentad, 1959**	Elevated C-reactive protein
	Fever	Abnormal liver tests
	Right upper quadrant pain	Aspartate aminotransferase
	Jaundice	Alanine aminotransferase
	Septic shock	Alkaline phosphatase
	Altered mental status	γ-Glutamyl transpeptidase
		Imaging evidence of etiology (e.g., stone, stricture, stent)

negative blood cultures, requiring clinicians to have a high index of suspicion for cholangitis in selected circumstances and patient populations.

In addition to bacteria, viral, fungal, and parasitic pathogens have been reported in cases of pediatric cholangitis, particularly in immunodeficient patients (primarily patients infected with human immunodeficiency virus [HIV]) and patients with environmental exposure to parasites in endemic settings. Cholangitis due to viral infection is most commonly associated with hepatocellular disease with hepatotropic viruses, primarily cytomegalovirus (CMV), hepatitis C, and hepatitis B.[32,87,145] Depending on the clinical setting and age of the patient, CMV can have a markedly varied presentation, ranging from bile duct paucity seen in congenital CMV infection to hepatomegaly and jaundice in infants and children with primary CMV infection. The role of CMV hepatitis and cholangitis is significant in immunocompromised patients and solid-organ transplant recipients.

Fungal cholangitis, specifically with *Cryptococcus neoformans* or *Candida albicans*, has been reported in immunocompromised and immunocompetent patients.[44,140,151] Hepatobiliary dysfunction may be the initial manifestation of disseminated infection.

The biliary tree also is susceptible to parasitic infections in normal hosts. Nematodes—*Ascaris* and, rarely, *Strongyloides*—commonly cause biliary disease in endemic regions. Migrating *Ascaris* larvae may cause a direct inflammatory response if they pass through the biliary system, or, more commonly, a high worm burden can cause an obstruction leading to secondary pyogenic cholangitis.[131,235] Liver flukes, such as *Opisthorchis* (formerly *Clonorchis*) *sinensis*, *O. viverrini*, and *O. felineus*, also may pass through the biliary system through their life cycle.[162] Of these trematodes, *Clonorchis* is found frequently in cases of recurrent pyogenic cholangitis in Asian children.[282] Similar to the worms, the migration of the flukes *(Fasciola hepatica)* through the biliary tree may induce primary inflammation and, later, a secondary bacterial infection. Echinococcal cholangitis has been described in the setting of obstruction secondary to cyst formation from infection with either *Echinococcus granulosus* or *E. multilocularis*.[34,90] Although *Cryptosporidium* spp. typically are known to cause cholangitis in the immunocompromised host, one case of a child without a documented immunodeficiency has been reported.[84] A thorough travel history should be obtained in all children presenting with new-onset cholangitis, in particular in patients in whom the most common causes are ruled out rapidly.

Finally, several cases of *Mycobacterium tuberculosis* cholangitis mimicking cholangiocarcinoma in immunocompromised and immunocompetent hosts have been reported in the adult literature.*

CLINICAL PRESENTATION

The classic presentation of cholangitis first described by Charcot in 1877 and known commonly as the *Charcot triad* is reported in 50 to 70 percent of patients with cholangitis in most studies (Table 48-2).[19,186,251,272] It combines the clinical findings of fever, right upper quadrant pain, and jaundice.[41] The Reynold pentad added septic shock and altered mental status to the Charcot triad.[208] More recently, the Tokyo guidelines updated diagnostic criteria for cholangitis to include laboratory evidence of an inflammatory response, abnormal liver test results, and imaging findings of biliary dilation or evidence of etiology of underlying disease.[272] Studies in children show that fever is the most common presenting symptom, occurring in 100 percent of 105 patients with cholangitis after undergoing HPE.[63] In addition, either acholic stools or an increase in serum bilirubin concentration occurs in 68 percent of patients. Older children and teenagers with cholangitis typically report abdominal pain that may or may not be associated with meals or localize to the right upper quadrant. Patients may report new-onset pruritus as a consequence of retained biliary constituents. Laboratory findings include elevated white blood cell count and C-reactive protein, bilirubin, and alkaline phosphatase values.[285]

The findings of cholangitis may be markedly attenuated in infants and immunocompromised patients, suggesting that a low threshold for suspicion be employed in the evaluation of these children at risk. The presentation of cholangitis in an infant with biliary atresia, status post Kasai portoenterostomy, may be as varied as lethargy, increasing jaundice, abdominal tenderness, or fever alone. Finally, patients with ongoing hemolysis (e.g., patients with hemoglobin SS disease) are at high risk for

*References 14, 70, 136, 193, 202, 267.

developing cholecystitis and cholangitis from bilirubin stones, yet the symptoms may readily overlap with other causes of abdominal pain.

DIAGNOSTIC EVALUATION

Physical examination may reveal a varied range of toxic appearances, with vital signs suggesting serious systemic infection in more advanced cases (fever, tachycardia, hypotension). Physical examination typically reveals icteric sclera and a distended abdomen, with tenderness localized to the mid or right upper quadrant. Palpation of the liver edge may reveal tenderness. Laboratory studies may reveal an elevated erythrocyte sedimentation rate (81%), leukocytosis or leukopenia (56%), and increased serum levels of conjugated bilirubin.[63] Laboratory evaluations in children should include a standard complete blood cell count with differential and liver panel (alanine aminotransferase, aspartate aminotransferase, alkaline phosphatase, γ-glutamyltransferase, and fractionated bilirubin [unconjugated and conjugated]). The differential diagnosis of fever, abdominal pain, and jaundice also should include sepsis and hepatitis. No single laboratory test or combination of tests can establish a diagnosis of cholangitis.[251,285]

Attempts at identifying a microbiologic agent should be made. Blood and bile cultures should be performed at all available opportunities and specimens drawn before antimicrobial therapy is initiated.[255] Most cases are polymicrobial, with a predominance of gut-derived organisms (see Table 48-1). Some studies report positive blood cultures in 21 to 71 percent of patients with acute cholangitis.[96,251,277] Other investigators have reported identification of organisms in blood in 10 to 25 percent of patients, which is similar to our experience.[277] In patients with a history of hepatobiliary surgery, aerobic and anaerobic cultures should be considered; and in virtually all cases of young children with abdominal pain and jaundice, a urine culture should be considered.

The role of liver biopsy to evaluate the parenchyma for evidence of cholangitis is controversial, but occasionally this testing may have a place in the setting of negative blood cultures. When used along with blood cultures, hepatic cultures have been shown to increase the diagnostic yield of identifying a microbiologic organism to 75 percent of patients, whereas histologic confirmation of cholangitis may be the only firm evidence of biliary tract infection in some cases.[63] In practice, liver biopsy is performed infrequently and patients are treated empirically. In cases of gallstone-associated biliary tract obstruction with cholangitis that requires endoscopic or surgical decompression, bile should be obtained and cultured at the time of the procedure. In an adult study, 22 of 23 patients with gallstone-associated cholangitis were found to have positive bile cultures.[149]

The initial and principal radiologic evaluation for suspected cholangitis is transabdominal ultrasonography, with the primary goal being to search for evidence of biliary tract obstruction, usually associated with dilation of the common bile duct or intrahepatic ducts. Ultrasound examination may reveal anatomic biliary tract abnormalities (choledochal cyst), intrahepatic cysts or fluid collections, and hepatic or other intra-abdominal masses. Other noninvasive imaging modalities include computed tomography (CT) and magnetic resonance cholangiopancreatography (MRCP), which provide increasingly detailed images of the intrahepatic and extrahepatic biliary anatomy.*

Taken together, these noninvasive imaging techniques should be able to detect the presence of biliary tract obstruction and some congenital anatomic anomalies, although even experienced ultrasonographers still may miss small stones and sludge, especially in the common bile duct. It is important to recognize the technical limitations of the methodology and the possible presence of undetected stones or sludge in the gallbladder or common bile duct (choledocholithiasis) as a cause of biliary tract dilation. The sensitivity of ultrasound for choledocholithiasis is poor, ranging from 30 to 50 percent.[46,47,234] Sensitivity improves to approximately 90 percent with CT, and from 95 to 99 percent with ERCP.[203]

Newer modalities, including endoscopic ultrasound, laparoscopic ultrasound, and helical CT cholangiography, may improve detection in certain patient populations. The 2002 National Institutes of Health State-of-the-Science Consensus conference regarded endoscopic ultrasound, MRCP, and ERCP to have comparable sensitivity and specificity in detecting common bile duct stones.[182] In the hands of an experienced echoendoscopist, endoscopic ultrasound has been shown in adults to be the procedure of choice to identify small stones and sludge in the common bile duct. This method may prove useful in children as well and may prevent the unnecessary use of ERCP and the risk of its associated complications.[214,234,270]

After HPE has been performed, imaging may be able to identify lakes of retained bile (bilomas), which may be a source of infection, in a patient with biliary atresia. Nuclear medicine (hepatobiliary iminodiacetic acid [HIDA]) scans have a limited role in the evaluation of cholangitis. HIDA scans may be most helpful in determining if a patient has a complete obstruction of the common bile duct or if an isolated obstruction of the cystic duct (e.g., cholecystitis) is present.

Because of the inherent risks associated with invasive procedures in these infants, percutaneous drainage of bilomas for culture or other purposes rarely is performed. Similarly, percutaneous drainage is preferred to ERCP for anatomic reasons. Invasive imaging has a role, especially when it may be coupled with therapeutic decompression of an obstructed, and potentially infected, biliary tree. ERCP has proved to be extremely useful in the evaluation and management of biliary tract obstruction and should be considered in the management of a child with evidence of an obstructed common bile duct.† The role of ERCP in infants and small children is limited by the number of trained pediatric gastroenterologists and should be considered in tertiary or quaternary care centers that have the requisite expertise. ERCP allows obtaining bile for microbial and chemical analysis and

*References 72, 174, 213, 223, 232, 262.
†References 5, 74, 157, 236, 237, 241.

provides detailed imaging of the biliary tree. Significant technical advances have occurred in biliary endoscopy, such that direct visualization of the bile ducts (choledochoscopy) with the ability to obtain direct sampling is possible in children.[98,238] Acute cholangitis alone is an indication for ERCP when choledocholithiasis is suggested.[161]

Practically, ERCP may detect (and remove) small stones and sludge that are missed by ultrasound, CT, or MRCP. ERCP is helpful in establishing the differential diagnosis of biliary tract diseases, such as PSC, which may manifest in a fashion similar to that of infectious cholangitis but have a characteristic radiographic appearance. In the future, as the use of endoscopic ultrasound in pediatrics increases, ERCP may be reserved for those patients in whom stones or sludge have been found by endoscopic ultrasound or in patients with a high pretest probability of having choledocholithiasis (e.g., patients with sickle-cell conditions).[75,161,234] Any child with a first episode of cholangitis warrants a detailed investigation of a possible underlying biliary tract anatomic abnormality using at least one of the available diagnostic modalities.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis for an acutely ill child with fever and clinical evidence of hyperbilirubinemia is broad; a thorough workup must include consideration of infectious and noninfectious causes (Table 48-3). A thorough investigation for any hepatic and biliary tract pathologic process with blood and radiologic studies must be initiated to evaluate for stones or other obstructive processes that may cause symptoms characteristic of the Charcot triad.

Acute viral hepatitis may manifest in numerous ways but often begins with nonspecific signs: fever, headache, anorexia, and jaundice.[71] Laboratory studies typically reveal a greater elevation of serum aminotransferase levels (alanine aminotransferase and aspartate aminotransferase) than the biliary tract enzymes alkaline phosphatase and γ-glutamyltransferase. In a child with no other evidence of biliary tract obstruction, screening assays for hepatitis infection are warranted.

TABLE 48-3 **Differential Diagnosis of Fever, Abdominal Pain, and Jaundice**

Cholangitis
Cholecystitis
Cholelithiasis
Sepsis
Hepatitis
Choledochal cyst
Pancreatitis
Urinary tract infection
Leptospirosis and other systemic infections with hepatic involvement
Spontaneous perforation of common bile duct
Biliary cyst
Appendicitis

Pyogenic liver abscesses and amebic abscesses tend to manifest as fever, abdominal pain, hepatomegaly, and focal right upper quadrant tenderness.[171] Laboratory findings vary. CT is considered to be the most sensitive technique for evaluation of these diagnoses.[174] Numerous bacterial, parasitic, and spirochetal infections also should be considered in the differential diagnosis, including, but not limited to, typhoid fever, brucellosis, leptospirosis, borreliosis, amebiasis, and malaria. It is beyond the scope of this chapter to expand on the systemic infections associated with hepatic involvement.[192] Recurrent pyogenic cholangitis is another consideration, although it is rare in the Western Hemisphere and even more so in the pediatric population.[222]

Jaundice may occur with sepsis of any cause, more commonly in a critically ill infant or child. Clinical evaluation may show a predominantly direct (conjugated) hyperbilirubinemia usually accompanied by a modest elevation of γ-glutamyltransferase, although serum transaminase levels may not be elevated. These findings are caused by a hepatocellular cholestasis, owing to humoral mediators of sepsis (i.e., endotoxin and proinflammatory cytokines), but they can be exacerbated by biliary sludging that accompanies septicemia. Although sepsis-associated cholestasis historically was linked primarily to gram-negative sepsis, it can be seen in all forms of infection. In some cases, radiologic workup or biopsy is warranted to rule out ductal obstruction or a pathologic process of the biliary tract. Jaundice may occur as the sole presentation of sepsis in infants and children[61]; however, research into sepsis-induced cholestasis points to a complex, multifactorial etiopathogenesis.[40,80,175,264]

Drug-induced cholestasis tends to occur acutely with the onset of jaundice, pruritus, and other symptoms that may mimic cholangitis. It rarely is associated with fever, however. Among the main classes of drugs commonly used in pediatric practice that may lead to significant hepatotoxicity are antimicrobial agents (mainly trimethoprim-sulfamethoxazole [TMP-SMX], amoxicillin/clavulanate, clindamycin, minocycline, nitrofurantoin, erythromycin, cephalosporins, isoniazid, rifampicin, fluconazole), anticonvulsants (phenytoin, carbamazepine, valproate, felbamate), nonsteroidal anti-inflammatory drugs (aspirin, ibuprofen), antihypertensive agents (propranolol, diltiazem),[30,45] and herbal remedies such as kava kava. Although rarely used in pediatric patients, statins may also lead to significant hepatotoxicity.[45] If the offending agent is identified in time, removing it typically leads to rapid improvement. Ceftriaxone warrants special mention because it has been linked directly to cholangitis and cholecystitis, possibly as a result of its biliary concentration and precipitation, leading to sludge and stones.[134,183]

Other systemic illnesses may occur with fever and evidence of a pathologic process of the biliary tract, and their presentations may overlap with presentations of infectious cholangitis. PSC is defined as a chronic inflammation of the intrahepatic or extrahepatic ducts leading to a range of biliary tract pathologic processes, from

dilation to obliteration and periductular fibrosis. PSC is seen most commonly in patients with inflammatory bowel disease and affects adolescent boys with inflammatory bowel disease more commonly than girls. Symptoms include systemic findings, such as fatigue, malaise, and weight loss, and evidence of cholangitis, including fever. PSC must be suspected in a jaundiced patient with inflammatory bowel disease or in an adolescent presenting for the first time with jaundice.[147] Diagnosis is established best by ERCP or magnetic resonance cholangiography showing irregular narrowing and stricture of the hepatic and common bile ducts and the intrahepatic ducts.[159,210] Patients with PSC are at risk for developing intrahepatic and common bile duct strictures, with subsequent obstruction, sludge or stone formation, cholangitis, and, ultimately, cholangiocarcinoma.[113,147]

TREATMENT

Therapeutic goals in the treatment of cholangitis should include general support of the patient, early initiation of appropriate antibiotic therapy, and, in cases of obstruction by stones or stricture, decompression of biliary obstruction via ERCP or surgery. Consulting pediatric surgeons early in the course of evaluating a patient with suspected cholangitis generally is helpful. The importance of decompression and drainage of the bile tract in the presence of systemic infection secondary to cholangitis cannot be overemphasized. Other potential causes of obstruction, such as choledochal cysts, ultimately require surgical consultation and repair.

Initial and conservative management should include appropriate inpatient monitoring, cessation of oral intake with intravenous fluid support, parenteral antibiotic therapy, and supportive management as warranted by the child's clinical status. Antimicrobial agents are selected to cover suspected or documented organisms based on local or documented susceptibility patterns and the ability to achieve adequate serum and tissue concentrations. Currently, no single antibiotic or combination is recognized universally as being the definitive therapy for cholangitis in children. Parenteral antibiotics are indicated in almost all cases of children with suspected biliary tract sepsis. Theoretically, the ability to achieve high biliary concentrations (Table 48-4) should be considered. However, clinical and experimental data are lacking to strongly support the recommendation for sole use of antimicrobial agents with excellent biliary penetration. Adequate serum levels may be sufficient.[2,59]

Empirical antibiotics should cover the most commonly isolated enteric pathogens, including *E. coli*, *Klebsiella* spp., and *Enterococcus* spp. Previously, a combination of ampicillin or penicillin with an aminoglycoside was considered a standard regimen for cholangitis, with a clinical cure rate of 40 to 95 percent in various adult studies.[39,81,177,255,260] Multiple recent studies show equivalent effectiveness of newer agents, including penicillin plus β-lactamase inhibitor combinations, third- and fourth-generation cephalosporins, and carbapenems.[81,116,259,260]

TABLE 48-4 **Distribution of Antibiotics Used to Treat Cholangitis**

†Ureidopenicillins such as pipercillin.
Data from references 16, 27, 106, 128, and 277.

The general recommendation for treatment of a pediatric patient with suspected cholangitis is a semisynthetic penicillin plus β-lactamase combination or a third-generation cephalosporin with or without an aminoglycoside.[66,139,277] The ureidopenicillins (e.g., pipercillin plus tazobactam) exhibit broad-spectrum activity against gram-positive streptococci, gram-negative bacilli, and many anaerobes. If a cephalosporin is used in a child with clinical sepsis, it is reasonable to consider the addition of metronidazole for anaerobic species, particularly *Bacteroides* spp.[29] Rothenberg and colleagues reported a 63 percent success rate in the treatment of pediatric patients with cholangitis after HPE using imipenem-cilastatin or third-generation cephalosporins with or without aminoglycosides and a 58 percent success rate using semisynthetic penicillins with aminoglycosides.[217] As mentioned previously, ceftriaxone probably should be avoided because it has been associated with biliary sludging and cholecystitis.[117] Although carbapenems provide very broad-spectrum coverage of enteric organisms associated with bacterial cholangitis,[217,242,269] these agents should be reserved for treatment of extended-spectrum β-lactamase producers or other multidrug-resistant pathogens. Antibiotic resistance is encountered more often in patients with repeated episodes of cholangitis.[63] Empirical broad-spectrum treatment should be narrowed to target specific pathogens as soon as culture results are available to avoid emergence of antimicrobial resistance or overgrowth of flora leading to secondary infection (e.g., *Clostridium difficile*, yeast).[144,255]

Antibiotic efficacy is determined by clinical and laboratory parameters, such as defervescence and improvement in biliary excretion. Duration of antibiotic treatment in adult guidelines is as short as 2 to 3 days; however, a short course may result in recurrence in pediatric patients.[217] The recommended course of therapy is 14 to 21 days, with longer duration recommended in special cases, such as recurrent or refractory cholangitis, and in the case of intrahepatic abscesses or hepatic surgery. Long-term administration of antibiotics without rationale should be avoided.[255] Although oral antibiotic therapy generally has no place in the treatment of cholangitis in children, oral ciprofloxacin has been used in some adult populations.[277]

Ultimately, cholangitis, or the risk thereof, will not resolve in the presence of ongoing biliary obstruction. Although antibiotic therapy may treat septicemia, timely establishment of biliary drainage is imperative to relieve the obstruction and to increase biliary penetration of antibiotics.[65,144] In 20 to 25 percent of adults with cholangitis, medical therapy is insufficient and decompression via ERCP (or laparotomy) is indicated.[9,65,127,221] Furthermore, almost all patients who improve with medical therapy alone will ultimately require bile duct clearance to prevent recurrence of cholangitis.[144] ERCP and percutaneous transhepatic cholangiography generally are recommended as first-line approaches because they pose a lower risk than does open surgical intervention.[195] Although ERCP can be diagnostic in the case of biliary obstruction, it also provides therapeutic options with sphincterotomy, stone removal or destruction, or stent placement.

Treatment of parasitic cholangitis should include appropriate treatment of biliary parasites based on regional sensitivities in addition to antibiotic coverage of secondary bacterial infections. Endoscopic or surgical intervention may be required to remove worms or cysts from the biliary tree.[85,201]

PREVENTION

Treatment of biliary obstruction is the primary means to prevent acute bacterial cholangitis. Long-term prophylactic antibiotics are not recommended. Although a few case reports and small case series have documented success with TMP-SMX, ciprofloxacin, and neomycin as prophylactic antibiotics,[31,43,109,173] there are no data showing significant benefit compared with patients without prophylaxis in controlled studies. Moreover, development of highly resistant bacteria selected by continuous use of antibiotics has been documented.[35,63,226]

Antibiotics immediately prior to biliary tract surgery do play a role in prevention of wound infection rates.[169] The role for antibiotic prophylaxis before ERCP is less clear.[277] Antibiotics are recommended if biliary stone clearance is not anticipated during a single ERCP session; otherwise, prophylaxis is unlikely to be useful.[11]

COMPLICATIONS

Regardless of the patient's age at the time of presentation, cholangitis can be life threatening. Other morbidities associated with cholangitis include biloma formation and pancreatitis. Because pediatric patients who present with cholangitis typically have an underlying biliary or liver pathologic process, cholangitis may precipitate a rapid exacerbation of the underlying disease and potentiate cirrhosis, portal hypertension, severe gastroesophageal bleeding, or ongoing sepsis. In diseases such as biliary atresia, cholangitis may hasten the patient's course toward requiring organ replacement. Cholangitis is an important determinant of long-term survival after HPE, but it is unclear if it is a determinant of transplant survival.[50-52,278]

SPECIFIC POPULATIONS AND CHOLANGITIS

Cholangitis and Biliary Atresia

In pediatrics, cholangitis is encountered most frequently in the setting of a patient with biliary atresia who has undergone a Kasai procedure. In 1959, Kasai and Suzuki first reported relief of biliary obstruction in children with biliary atresia by HPE.[124] The procedure, a Roux-en-Y hepatic portoenterostomy, is considered to be standard first-line surgical therapy for infants with biliary atresia, and it is associated with the highest success rates and long-term survival when performed early, usually by 60 days of life. Without this procedure, 90 percent of patients with biliary atresia die before reaching age 3 years, at an average age of 19 months.[99,123,125]

Cholangitis remains the most frequent complication of the Kasai procedure, occurring in 40 to 60 percent of patients.[189] A subgroup of patients with the pathologic finding of cystic dilation of the intrahepatic bile ducts seems to have the highest risk for developing postoperative cholangitis.[107] The development of cholangitis has been associated with a worsening in long-term prognosis of children with biliary atresia.[50,52,110] Complications of cholangitis are severe, ranging from inflammation and scarring, to alterations in biliary flow, and, eventually, to biliary cirrhosis. Repeated bouts of cholangitis are associated with worsening liver function, impaired growth, and need for early transplantation. For this reason, early detection, appropriate management, and prompt intervention and treatment of cholangitis are important in this population.

Most cases of post–Kasai procedure cholangitis occur within 1 year postoperatively. In a 1976 review of 49 cases of children who underwent the procedure, 31 achieved good bile flow restoration. Of these, 20 subsequently developed cholangitis, with 15 cases occurring within the first postoperative month and 3 within the second month.[187] Likewise, in a study of 105 cases of cholangitis developing in 101 children after they underwent hepatic portoenterostomies, Ecoffey and colleagues[63] showed that 63 percent of the cases occurred within 3 months after surgery and 93 percent occurred within 1 year. Rarely, late cholangitis may occur and has been reported to occur several years after HPE.[86]

The generally accepted mechanism for development of cholangitis after a Kasai procedure is ascending bacterial colonization. This theory is reinforced by reports of a higher incidence of cholangitis developing in patients with good or partial bile flow after the Kasai procedure (78%) than in patients with no obvious bile flow (13%).[63] A 1978 study of 19 patients concluded that all bilioenteric conduits after the procedure were colonized within 1 month, correlating with the high incidence of symptomatic infection at this early stage.[105,106] The retrograde bacterial colonization may be enhanced by overall changes in intestinal motility after the Roux-en-Y loop.[252] Over time, the intestinal conduit from hepatic porta to jejunum seems to "mature," and the number of episodes of cholangitis diminishes. How this adaptation happens is unknown. Late episodes of cholangitis, occurring 1 to 2

years after a Kasai procedure, likely are related to mechanical obstruction, such as adhesions, and warrant investigation.[150]

Gram-negative enteric organisms constitute most organisms causing ascending cholangitis after HPE. *E. coli* has been found in 50 percent of the first and second cholangitis episodes and in decreasing frequency in subsequent episodes.[63] Anaerobes also are common findings and should be considered when selecting antibiotic treatment.[29] Refractory or recurrent cases occurring after surgery may warrant consideration of fungal disease, principally *Candida* spp.[44] Attempts to isolate an organism generally are made, but blood cultures typically have a low yield.[217] Bile cultures tend to reflect the multiple enteric organisms that colonize the conduit but may not specify the true pathogens. Percutaneous liver biopsy has been used successfully to obtain cultures, but as in other forms of cholangitis it rarely is used for this purpose.[188]

In the intraoperative and postoperative management of children with biliary atresia, attempts have been made to prevent the incidence of cholangitis. Various modifications in the surgical configuration of the intestinal conduit have been suggested to reduce enteric reflux. Initial studies have documented a reduced incidence of ascending cholangitis in the presence of a surgically placed antireflux valve.[24] Despite the reduction of intestinal reflux in these cases, cholangitis continues to occur.[24] Cases of refractory cholangitis may require surgical intervention, especially if obstruction of the conduit or porta hepatis is suspected. Absolute indications for reoperation after HPE are unclear; however, a recent series demonstrated positive outcomes with the primary indication of recurrent jaundice.[22]

The role of corticosteroids in improving biliary drainage is controversial and has not been the subject of rigorous controlled trials. Perioperative corticosteroid pulses, typically a 3- to 5-day course of intravenous methylprednisolone, have been shown, however, to be clinically beneficial by decreasing temperature, increasing bile flow, and improving liver biochemistries.[143,178,217] A multicenter, randomized, double-blind, placebo-controlled study sponsored by National Institutes of Health is in progress in the United States to assess the safety and efficacy of using corticosteroids after the Kasai procedure.* The forthcoming results of this study should yield definitive information regarding the postoperative management of these children. The incidence of cholangitis in the treated and untreated arms is one of the outcomes.

In addition, some centers advocate the use of prophylactic antibiotics, typically TMP-SMX. The benefits of this practice are not well established, however (see Prevention).[43] In adults with recurrent cholangitis secondary to fixed obstruction, as in the case of malignancy, TMP-SMX and ciprofloxacin have been shown to be helpful in preventing episodes.[268] When used, TMP-SMX is used as a first-line agent. In selected patients with recurrent episodes of cholangitis on TMP-SMX and a functional HPE, we have used oral ciprofloxacin successfully.

*http://clinicaltrials.gov/ct2/show/NCT00294684?term=basitrank=3

In patients with post–Kasai procedure biliary atresia, each episode of cholangitis is associated with a 1 percent mortality risk. In a recent longitudinal series, 30 percent of patients who died with biliary atresia without transplant had sepsis, several with suspected or proven cholangitis.[50] Some studies suggest that no significant clinical difference exists in overall survival rates between patients who have undergone the Kasai procedure and have or have not had cholangitis.[189] Previous studies suggest, however, an 88 percent mortality rate among patients who develop cholangitis within 1 month after undergoing the Kasai procedure and 16 percent in patients who develop it more than 1 month later. More recent studies suggest that the occurrence of cholangitis is related to early postoperative mortality, and the number of repeated episodes is inversely related to survival.[283] Thus, patients with recurrent episodes of cholangitis are considered for liver transplantation.

Cholangitis After Liver Transplantation

Infection remains the most common reason for morbidity and mortality after pediatric liver transplantation, accounting for 20 to 30 percent of postoperative deaths.[219,247] Bacterial infection that develops after transplantation tends to occur within the first 2 months postoperatively and generally is of either respiratory tract or intra-abdominal origin. Among patients with severe bacterial infections of intra-abdominal origin, cholangitis and biliary tract infections commonly develop. Gram-negative aerobic bacteria are encountered most commonly in this setting.[224] One adult study showed that 18 percent of 284 patients receiving liver transplantation had confirmed episodes of cholangitis.[273] Pediatric data suggest that the rate of cholangitis after liver transplantation for biliary atresia is 5 to 11 percent.

Biliary tract disease frequently occurs after the post–liver transplantation complication of hepatic artery thrombosis.[158,165] This complication was more prevalent in the early days of pediatric liver transplantation but decreased owing to the use of microsurgical techniques. Hepatic artery thrombosis eventually leads to damage of the bile duct because the biliary blood supply is exclusively arterial, whereas the hepatic parenchyma is vascularized by the portal vein and the hepatic artery. Biliary injury leads to altered biliary anatomy and drainage, increasing the risk for development of infection in these patients. Although the majority of pediatric liver transplant recipients have a Roux-en-Y biliary-enteric anastomosis from the donor bile duct to the recipient bowel, ascending cholangitis is rare in this population. In patients with a duct-to-duct anastomoses, cholangitis secondary to stricture formation or intraductal lithiasis can be treated by ERCP.

Cholangitis that develops after liver transplantation may manifest as fever, jaundice, elevated aminotransferase and bilirubin levels, and bacteremia. The variable nature of an immunocompromised patient's response to infection renders the reliability of each of these signs and symptoms unique to each occurrence. Distinguishing these symptoms from the presentation of posttransplant rejection or infection (e.g., with CMV or Epstein-Barr

virus) is important. For this reason, liver biopsy often is a necessary part of the evaluation of a posttransplant patient with fever and elevated liver tests.

Cholangitis in Immunocompromised Patients

Although biliary disease related to acquired immunodeficiency syndrome (AIDS) may be considered the most common cholangiopathy of immunocompromised hosts, it is not the most frequent one in pediatric practice. Cholangitis also may occur in children with non-AIDS immunodeficiency. Sclerosing cholangitis has been reported in cases of primary immunodeficiency, including familial T-cell deficiency, IgA/IgG deficiency, and X-linked hyper-IgM syndrome.[89,148] Patients with sclerosing cholangitis often present with superimposed bacterial cholangitis because of poor biliary drainage. Opportunistic hepatobiliary infection also has been reported in children with leukemia.[79,137,240]

AIDS-related cholangitis is a well-known complication of AIDS. It tends to occur late in the course of the illness and is more common in adults than in children. With the decline in the number of new AIDS cases in the United States, especially in pediatric patients, this diagnosis has become rare. In 1989, Cello described four distinct patterns of disease in AIDS-related cholangitis as seen on cholangiography—papillary stenosis, sclerosing cholangitis, combined papillary stenosis and sclerosing cholangitis, and long extrahepatic bile duct strictures.[38] The pathogenesis of these changes is unknown and may be related to biliary inflammation secondary to immunodeficiency, infiltration of the mucosa by HIV itself, or opportunistic infection by known gut culprits in AIDS infection.

Opportunistic agents most commonly responsible are CMV, *Cryptosporidium*, Microsporidia, and, uncommonly, *Mycobacterium avium-intracellulare* and *Isospora*.[181,289] One report of unexplained cholangitis in a small cohort of HIV-positive men identified *Enterocytozoon bieneusi* in the bile of all of the patients.[198] Although AIDS cholangiopathy is extremely rare in children, these pathogens can be found in pediatric patients with primary immunodeficiencies and associated PSC and with secondary immunosuppression after undergoing solid-organ transplantation.[1,57,167,211,279]

Clinical presentation is similar to that in non-HIV patients, with the exception of jaundice, which tends to be less common. In a series of 45 adults with AIDS-related cholangitis, abdominal pain was reported as the most common presenting symptom, occurring in 64 percent of patients, followed by diarrhea (22%), fever (20%), and jaundice (7%).[60] Twenty percent of patients were asymptomatic and identified by routine blood work alone.[60] A 1997 review reported that 90 percent of adults present with right upper quadrant or epigastric pain.[181] Cholangitis has been reported as the initial presentation of HIV infection in a few patients.[23,176]

Diagnostic steps include noninvasive imaging with ultrasonography and CT. ERCP can also be useful. Abdominal ultrasonography is abnormal in 75 percent of patients and typically shows dilation or wall thickening of the common bile duct. These findings, along with liver function studies, may be suggestive of the disease even in children.[37,218] ERCP can show further characteristic changes in the biliary tract and has the added advantage of obtaining specimens for biopsy and culture and the possibility of therapeutic intervention.[284] Although AIDS-related cholangitis typically is not directly associated with mortality, most patients with AIDS-related cholangitis die within 1 year of being diagnosed because cholangitis usually occurs in patients with end-stage disease.[156] Therapy generally is symptomatic and should include coverage of bacterial cholangitis, which often is associated because of impaired biliary drainage.

Cholangitis in Association with Congenital Anatomic Abnormalities: Choledochal Cysts and Caroli Disease

Choledochal cysts occur in 1 in 15,000 births in Western nations and 1 in 1000 live births in Japan.[64,154,243,246] Typically, presenting signs suggest cholestasis and may include jaundice, dark urine, and acholic stools, or patients may present with abdominal masses with or without jaundice. If diagnosed late or untreated, choledochal cysts may result in severe complications secondary to biliary tract obstruction, including cholangitis and pancreatitis. One series of 36 Indian patients reported 13 patients, more frequently children than infants, who presented with cholangitis.[197] Cholangitis is more likely to be the presenting sign for choledochal cyst in adult patients.[42]

Treatment of cholangitis associated with choledochal cysts involves supportive treatment of the patient, including appropriate antibiotic treatment. In the past, cystenteric drainage procedures were used as temporizing treatments, and this type of repair was associated with high rates of complications, including recurrent bouts of cholangitis, stones, and cholangiocarcinoma in the remnant duct.[209] The current surgical goal is complete surgical excision; compared with internal drainage procedures, this approach is associated with lower rates of postoperative cholangitis and mortality.[181] Five types of choledochal cysts have been identified, with solitary extrahepatic cysts (type I) being encountered most frequently. After this type of cyst has been excised, reconstruction of the biliary tract may involve a Roux-en-Y choledochojejunostomy or hepatojejunostomy.

Patients who undergo this surgery also are at risk for developing postoperative ascending cholangitis, with an incidence of 8 to 19 percent.[73,227] Although recurrent cholangitis may lead to chronic liver disease in the long-term, antibiotic prophylaxis is not recommended routinely.[119]

Caroli disease describes congenital dilation of the intrahepatic and extrahepatic biliary tree characterized by pure ductal ectasia.[54,55] More commonly, dilation of the intrahepatic ducts is attributed to ductal plate malformation in association with congenital hepatic fibrosis. The association of ductal ectasia with congenital hepatic fibrosis is more common than without and is termed

Caroli syndrome. Both of these diseases may manifest as clinical signs of liver disease or renal disease secondary to the associated condition of autosomal recessive polycystic kidney disease, or both.[120,152,190] Dilation of the intrahepatic bile ducts results in biliary obstruction and places the patient at increased risk for development of intrahepatic stones and cholangitis, which significantly increases morbidity and mortality rates in Caroli disease and congenital hepatic fibrosis. Diagnosis is suspected in the case of recurrent cholangitis or portal hypertension of unknown etiology and can be confirmed by ultrasound or cholangiography (MRCP, ERCP, or percutaneous transhepatic cholangiography).[69]

Portosystemic shunting is considered the treatment of choice because this condition typically does not progress to liver failure. Suspicion of cholangitis, whether owing to signs of infection or sepsis or to laboratory results suggesting inflammation, should be confirmed via a diagnostic liver biopsy for culture. Treatment of cholangitis in the setting of Caroli disease may be difficult. Recurrent episodes may occur even after administration of intensive intravenous antibiotic therapy.[274] In some cases, drainage procedures may be used for refractory or recurrent infections. Orthotopic liver transplantation is the treatment of choice in recurrent, life-threatening episodes of cholangitis.[97,274]

Typically, patients with Caroli disease or Caroli syndrome present with cholangitis because the biliary malformation communicates with the extrahepatic biliary tree. Rarely, patients are seen with hepatic cysts associated with autosomal dominant polycystic kidney disease. These lesions are noncommunicating lesions and as such are not prone to infection. In the absence of a history of cholangitis, it is advisable that these rare patients not undergo invasive procedures of the biliary tree because of the risk for microbial seeding and subsequent suppurative cholangitis.[6,130,287]

Cholangitis After Endoscopic and Other Biliary Procedures

The overall complication rate for pediatric ERCP is reported from 0 to 11 percent and in adults cholangitis is a known complication of ERCP. In a series of 50 pediatric patients, low-grade fever, abdominal pain, nausea, and vomiting were reported as the most common complaints after undergoing ERCP; 1 patient was treated for mild cholangitis.[257] Another group reported three cases of sepsis in adults caused by multiresistant *Pseudomonas aeruginosa* after ERCP, ascribed to nosocomial transmission from the endoscope despite negative surveillance cultures.[58] In adults, and rarely in children, biliary sphincterotomy with or without stent placement can be used to alleviate a common bile duct obstruction, most frequently malignant.

The major complication of biliary stents is obstruction and subsequent upstream infection. The role of antibiotics or ursodeoxycholic acid to maintain stent patency has been examined and no conclusive evidence was demonstrated in favor of either one in the prevention of stent occlusion.[77,256] In certain children and adolescents with a history of recalcitrant cholangitis, percutaneous transhepatic biliary drainage is used by experienced centers to decompress the biliary tree upstream of the stricture or to dilate the stricture. This procedure is used primarily in patients with PSC and in transplant patients with biliary stenoses secondary to ischemia or rejection.* These patients may benefit from oral antibiotic prophylaxis, especially with ciprofloxacin because of its excellent biliary penetration.

CHOLECYSTITIS

Cholecystitis and its related complications are most commonly associated with cholelithiasis (gallstones); however, cholecystitis can occur without stone disease. An estimated 20 million individuals have gallbladder disease in the United States based on the National Health and Nutrition Examination Survey (NHANES) III report.[67] Although gallbladder-related diseases occur less often in children, there is a trend toward increasing rates of disease.[20,168] In one report from 2009, gallstones accounted for 4 to 6 per 100,000 hospital discharges in children younger than 15 years of age.[68] Recent data suggest that the obesity epidemic and related metabolic syndrome account for a greater proportion of gallstones in children.[122,168] Despite the predominance of obesity-related disease, children with hemolytic disorders remain at high risk for gallstones and related comorbidities. Similarly, several studies have reported much higher rates of complicated gallbladder disease in children than for adults, with common bile duct obstruction and gallstone pancreatitis occurring in up to 30 percent of children.[20,100,168]

Cholecystitis refers to inflammation of the gallbladder, which can occur in a variety of clinical scenarios. In adults, acute cholecystitis almost always is associated with gallstones—90 percent of adult cases occur secondary to gallstones. In contrast, 30 to 50 percent of pediatric cases are acalculous.[266] Acalculous cholecystitis is discussed separately at the end of this section. The most likely cause of calculous cholecystitis is gallstone obstruction of the cystic duct, which leads to increased intraluminal pressure with gallbladder distention, mucosal damage, and release of inflammatory mediators. The end result is acute inflammation of the gallbladder. Any bacterial infection is likely a secondary occurrence to biliary obstruction.[134]

ETIOLOGY AND PATHOGENESIS

Gallstones are divided into cholesterol or pigmented stones (black or brown), although they often are mixed

*References 12, 49, 77, 82, 95, 256.

in constituents. Stone formation occurs secondary to precipitation of insoluble bile content (cholesterol, bile pigments, and calcium salts). Cholesterol stones are formed when the balance of cholesterol, lecithin, and bile salts is such that cholesterol is no longer soluble and becomes supersaturated. Black pigmented stones can form when there is supersaturated bile or a decrease in the bile salt pool. This process includes an increase in bilirubin anions (as seen in unconjugated hyperbilirubinemia), an increase in unbound calcium, or a decrease in other factors that solubilize calcium and bilirubin.[126,191] Brown pigmented stones differ from black stones in that brown stones typically are more often related to infection and form within the common bile duct rather than the gallbladder in both children and adults. *O. sinensis* and *Ascaris lumbricoides* are major sources of brown pigmented stones in rural Asian countries.[103] Pigmented stones have been described with *E. coli*, *Pseudomonas* spp., *Staphylococcus* spp., *Enterobacter* spp., *Citrobacter* spp., and *Salmonella enterica* serovar Virchow.[15,53,265] There is also a strong relationship to urinary tract infections.[101] Ceftriaxone as well as other third-generation cephalosporins have been associated with cholelithiasis and sludge in this population, being reported in up to 38 percent in one series of children with biliary tract disease in Israel.[132]

The majority of data on children with pigmented stones comes from patients with hemolytic disease (e.g., sickle-cell anemia and thalassemia). There is a significant population of patients with biliary disease secondary to hereditary spherocytosis and other red cell membrane defects, pyruvate kinase deficiency, glucose-6-phosphate dehydrogenase deficiency, and autoimmune hemolytic anemia.[20,207,233] The prevalence of pigment gallstones in hemolytic disease increases with age. In children younger than 10 years old, the frequency is 12 to 14 percent; the frequency increases to 36 to 42 percent in individuals 10 to 20 years old.[21,230]

Until recently, pigmented stones were the predominant cause of gallstone disease and related morbidity in children in which up to 72 percent were involved.[76] However, in a recent 3-year report of over 400 pediatric patients with gallbladder disease, there was more than a threefold difference in obese patients with cholesterol stones compared with those with hemolytic disease.[168] This suggests a trend that children and adolescents are now more similar to adults with gallbladder disease than in years past.

Cholesterol stones are found most frequently in adults and have an increased prevalence in women from puberty to menopause and in obese patients.[225] Although boys and girls exhibit an equal incidence in gallstones at young ages, the incidence in girls increases significantly after puberty, and female predominance of gallstone disease continues through menopause.[68,185] Related risk factors for the presence of cholesterol stones in children and adolescents include ethnic background (Hispanic), obesity, pregnancy, and the use of oral contraceptives.[133,155,168,184] In addition, conditions that are associated with decreased ileal bile salt resorption predispose to stone formation. This association includes patients who have undergone ileal resection or bypass and patients with Crohn disease.[215]

TABLE 48-5 Conditions Associated with Pediatric Gallstone Disease

Biliary tract anomaly (e.g., choledochal cyst)
Cephalosporin use
Cystic fibrosis
Crohn disease
Genetic predisposition (e.g., *ABCB4, UGT1A1* mutations)
Hispanic or Latino ancestry
Hemolytic disorders (e.g., sickle cell anemia, hereditary spherocytosis)
Malabsorption
Metabolic syndrome
Obesity
Parasitic disease *(Ascaris lumbricoides)*
Pregnancy
Rapid weight loss
Solid-organ and hematologic transplant (e.g., liver, kidney, heart, bone marrow)
Total parenteral nutrition

Data from references 20, 76, 78, 141, and 168.

Total parenteral nutrition remains a significant risk factor for children to develop biliary tract disease and, in particular, gallstone formation.[204] This condition occurs more commonly in premature neonates, especially neonates with enteral diseases, in which prolonged fasting, sepsis, immaturity of the enterohepatic circulation of bile acids, small bowel bacterial overgrowth, and prolonged duration of total parenteral nutrition contribute to biliary stasis and increased prevalence of gallstones and sludge.* The occurrence of gallstones secondary to total parenteral nutrition does not lead to increased prevalence of complications, because many of these gallstones are clinically silent.

Gallstones in cystic fibrosis are common, with an estimated prevalence of gallstones in 10 to 30 percent. Symptomatic gallstones have been reported in 3.6 percent of affected pediatric patients.[244,271] Gallstones in cystic fibrosis are predominantly composed of a mixed pigment and smaller amounts of cholesterol. Stone formation is multifactorial but is related to altered lipid composition and altered motility.[102] Pathophysiology of pigmented stones in cystic fibrosis is also linked to ΔF508 mutations with fecal bile loss and altered enterohepatic circulation as well as *UGT1A1* mutations. Alterations in enterohepatic circulation have also been suggested as the mechanism for pigmented gallstone formation in Crohn disease.[26] Finally, children with chronic liver disease and, in particular, cholestasis are at increased risk for gallstone formation, owing to a deficit of biliary excretion.[280] The characteristics of the pediatric patient populations at risk for development of gallstones are summarized in Table 48-5.

In addition to the observations made in *UGT1A1* mutations, knowledge regarding the heredity of cholelithiasis continues to develop. A combination of genetic

*References 7, 129, 138, 196, 229, 253, 276.

predisposition and environmental risk factors is likely. In adults, a distinction is made between the "common" polygenic predisposition to gallstones and the rarer oligogenic predisposition. The first, polygenic group refers to patients with evidence of increased risk for developing biliary stone formation, including lithogenic *(LITH)* genes. The oligogenic group refers to a small group of patients with known mutations in genes involved in bile synthesis and export.[92,280] The clearest examples to date are defects in the *ABCB4* transporter in humans and the *Mdr2* homozygous null mutant in mice.[141,142,180,216] Both conditions lead to an increased propensity toward cholelithiasis and choledocholithiasis; however, whether these subjects have a profile of biliary tract infections different from that of the polygenic group is unknown.

CLINICAL PRESENTATION

Acute cholecystitis is characterized by abdominal pain with vomiting or nausea. The pain is referred to as "biliary colic" but is nonparoxysmal with a constant, sharp pain lasting 4 to 6 hours. Pain relents only if the obstructing stone in the cystic or common bile duct mobilizes but may persist or return with gallbladder wall inflammation. In children, differentiating between other forms of acute abdomen can be difficult because pain can be in the right upper quadrant but also exist in the mid epigastrium. Radiation to the left upper quadrant or the right shoulder can occur and, with peritoneal inflammation, poorly localize in the abdomen, corresponding to the gallbladder's somatic innervation.[239]

Jaundice is reported more frequently in younger children with acute cholecystitis and infrequently with acholic stools in infants. Although jaundice is typically associated in younger children, in one series of 50 children, no child younger than 6 years of age had jaundice.[204] If jaundice is present, choledocholithiasis or cholangitis should be strongly considered. Fever is not universally present in cholecystitis and has been reported to be as low as 11 percent in pediatric patients. Similarly, in a retrospective study of 198 adults who presented to an emergency department with acute cholecystitis, 71 percent were afebrile; of those with gangrenous acute cholecystitis, 59 percent were afebrile.[91]

Physical examination may reveal a tender right upper quadrant. On light palpation a small mass may be appreciated, corresponding to the swollen gallbladder. Contrasting this, the Murphy sign is positive when abdominal pain is elicited on deep palpation of the right upper quadrant corresponding to the liver edge or gallbladder and most apparent with deep inspiration. This can be appreciated during ultrasound examination and may be reported by the ultrasonographer. With a tense abdomen, rigidity suggests cholecystitis with local peritonitis and the patient may exhibit voluntary guarding or other peritoneal signs.

EVALUATION

Laboratory evaluation may show leukocytosis, although this finding is not universally present in adults or children with cholecystitis.[91,204] Even in gangrenous cholecystitis, up to 25% of patients may fail to have leukocytosis. Bilirubin levels may be elevated, especially in the setting of hemolysis. Conjugated hyperbilirubinemia may suggest cholangitis, choledocholithiasis, or sepsis-associated cholestasis. Friesen and Roberts reported 38 percent of patients with hyperbilirubinemia in a pediatric series, and levels of bilirubin to 4 mg/dL are reported in adults.[76,239] Serum aminotransferase, alkaline phosphatase, and γ-glutamyltransferase levels are also useful. Amylase and lipase values should be obtained because of the overlap of pancreatitis with both gallstone-related disease as well as viral hepatitides. Pediatric surgical consultation should be obtained in patients with possible acute cholecystitis or other forms of acute abdomen. However, if common bile duct obstruction or gallstone pancreatitis is suspected, pediatric gastroenterology consultation should be obtained for possible endoscopic management with ERCP.

Abdominal ultrasonography is the test of choice in establishing the diagnosis of cholecystitis. Findings include a thickened or irregular, hyperreflexive gallbladder wall with or without the presence of gallstones. Experienced sonographers may be able to elicit tenderness over the gallbladder, the "sonographic Murphy sign." Ultrasound is useful for detecting gallstones within the gallbladder in up to 90 percent of cases. However, the sensitivity of common bile duct stone detection is poor, ranging from 30 to 50 percent.[46,47,75] The finding of gallstones alone by sonogram does not indicate cholecystitis. Other false-positive studies may occur with the finding of thickened gallbladder walls in patients with hypoalbuminemia, renal failure, or heart failure.[194] The inability to visualize the gallbladder by ultrasonography may indicate the finding of a diseased, chronically obstructed gallbladder.[88]

Hepatobiliary scintigraphy (HIDA scan) can be useful in confirming the diagnosis of acute cholecystitis. The study employs a technetium-labeled iminodiacetic acid agent that is excreted into the bile ducts. Subsequent images are taken, which in a normal study should fill the gallbladder, extrahepatic ducts, and duodenum. In the case of cystic duct obstruction, a positive study fails to show the gallbladder filling. The sensitivity and specificity of this study are high, with results approaching 90 to 100 percent and 90 to 95 percent.[172,179,207] The test may be augmented by attempts to stimulate gallbladder contraction using a cholecystokinin analog.[94] Plain abdominal radiographs and oral cholecystography are rarely used in the modern era of biliary disease.

MANAGEMENT

The treatment plan for patients with gallstones depends on several factors, including patient symptoms, underlying conditions, and the presence of associated/concomitant choledocholithiasis. Asymptomatic patients with gallstones identified incidentally can often be managed conservatively, although guidelines in children are lacking. Symptomatic patients with large stones (>2 cm) may be considered for conservative nonoperative management or elective cholecystectomy.

Recommendations for evaluation of patients with sickle-cell disease include abdominal ultrasonography at 10 years of age.[249] When stones are detected, patients should be considered for early cholecystectomy, although this plan is controversial.[4,93,118,168,275] In patients with sickle-cell anemia, the benefit of timely surgery may outweigh the morbidity of associated abdominal pain crises and the overall morbidity and mortality of surgery in these patients, which increases with age. In patients with hereditary spherocytosis, ultrasound evaluation is recommended annually beginning at age 4, but severity of disease or coexistence of Gilbert syndrome may alter this.[254]

In acute calculous cholecystitis, laparoscopic cholecystectomy is the most common surgical treatment for children and is performed in over 95% of cases.[168] The preoperative management of patients includes hospital admission for monitoring, intravenous hydration, and pain control. Antibiotic therapy often is initiated, even without clinical evidence of sepsis or perforation. The choice of antibiotics is similar to that for cholangitis and typically covers gut luminal flora (e.g., a semisynthetic penicillin/β-lactamase combination or third- or fourth-generation cephalosporin with or without an aminoglycoside).[96,277,288] In high-risk patients in whom laparoscopic or open cholecystectomy is not feasible, cholecystotomy can be performed by interventional radiology or surgery. In adults, data suggest that early cholecystectomy should be performed in those with acute cholecystitis secondary to gallstone disease[205] and in biliary pancreatitis.[205]

The management of acalculous cholecystitis may vary based on whether it is acute or chronic, but overall limited data are available. In addition to treatment of underlying causes, options for therapy in acute acalculous cholecystitis include nonoperative therapy with nothing by mouth and intravenous hydration and nutrition, cholecystostomy, or cholecystectomy.[114,266] The majority of patients with chronic acalculous cholecystitis undergo cholecystectomy. With findings of microlithiasis by endoscopic sampling or by endoscopic ultrasonography, consideration for ERCP or cholecystectomy may be appropriate to prevent cholangitis or recurrent pancreatitis.[121] The role of cholecystectomy for biliary dyskinesia, a motility disorder related to acalculous cholecystitis, is debated in children.[172]

COMPLICATIONS

Even with prompt recognition and therapy, acute cholecystitis may lead to complications. Perforation of the gallbladder is rare but can also occur in the cystic duct or bile duct. Mirizzi syndrome is a spectrum in which a cystic duct stone obstructs the common bile duct and in advanced forms can lead to fistulas and perforation. An inflamed, obstructed gallbladder may wall off to form an intraluminal abscess or empyema, although gangrenous inflammation of the gallbladder is rare in children. A localized perforation may develop into a pericholecystic abscess that is palpable as a tender right upper quadrant mass on examination. Free perforation with peritonitis is associated with a 30 percent mortality rate, but it is found in only a few patients, estimated at 1 to 2 percent of adult patients.[144] In both gangrene and perforation, intravenous fluids, antibiotic therapy, and surgical evaluation are critical.

However, the most common complication of cholecystitis is common bile duct obstruction or choledocholithiasis. Recent reports in children describe rates of obstructive jaundice and pancreatitis in up to 30 percent in those with symptomatic gallbladder disease.[20,100,168,204] Choledocholithiasis can lead to ascending cholangitis but is a rare cause of cholangitis in pediatric patients. Choledocholithiasis should be suspected in all patients with gallstones, along with right or left upper quadrant pain, jaundice, fever, or pancreatitis. Common bile duct stones originating from the gallbladder can be found in patients with acute cholecystitis by transabdominal or endoscopic ultrasonography, MRCP, ERCP, or intraoperative cholangiography. Although no formal recommendations are available in children, adult guidelines recommend the consideration of ERCP with stone clearance if suspicion is high for common bile duct stones. Patients with a total bilirubin greater than 4 mg/dL or a visualized stone by abdominal ultrasonography are at high risk for stones, as well as patients who have *both* a common bile duct diameter greater than 6 mm and a total bilirubin value greater than 1.8 mg/dL.[161] Modifications are likely necessary in children, owing to a smaller bile duct diameter. In patients at low risk for common bile duct stone or recently passed stones, laparoscopic cholecystectomy with or without intraoperative cholangiography is appropriate.[205]

Acalculous Cholecystitis

Acalculous cholecystitis is a rare but important cause of cholecystitis in pediatric patients. Generally, acalculous gallbladder disease in children occurs in various clinical settings, ranging from congenital gallbladder abnormalities, to idiopathic gallbladder distention without inflammation (acute hydrops of the gallbladder), to acute or chronic cholecystitis (Table 48-6). The exact pathogenesis of acute acalculous cholecystitis is unclear;

TABLE 48-6 **Conditions Associated with Acalculous Gallbladder Disease**

Biliary tract anomaly (e.g., choledochal cyst)
Bone marrow transplant
Burns
Chemotherapy in oncology patients
Critical illness in patients in intensive care units
Crohn disease, Henoch-Schönlein purpura, Kawasaki disease, systemic lupus erythematosus
Infectious agents (atypical microbes)
Microlithiasis
Postoperative state (e.g., cardiac surgery)
Sepsis
Sludge
Systemic inflammatory states
Total parenteral nutrition
Traumatic spinal cord injury

Data from references 112, 115, 212, 245, 261, and 263.

however, stagnation of the bile may be an important factor, as suggested by several predisposing clinical conditions that lead to bile stasis. In addition, sphincter of Oddi spasm or dysfunction, as occurs after administration of opiates, could lead to retrograde reflux of inflammatory enzymes or infectious agents. Alternatively, changes in the gallbladder vascular supply may weaken the gallbladder mucosa and allow biliary components to damage the gallbladder wall.[83] Acalculous cholecystitis has been associated with many infectious and noninfectious clinical scenarios. Bacterial, viral, and parasitic agents have been implicated in the setting of acalculous cholecystitis.

Frequently, gallstone or biliary microlithiasis missed by standard diagnostic evaluations may lead the clinician to the presumptive diagnosis of acalculous cholecystitis. One study in adults revealed that 33 of 35 patients with abdominal pain and a negative transabdominal sonogram had gallbladder sludge and stones, and 21 of those patients also had common bile duct involvement.[170]

Reports of true acalculous disease have been described with systemic infection from *Salmonella* spp., *Mycoplasma pneumoniae*, *Leptospira* spp., *Brucella* spp., Rocky Mountain spotted fever, group A streptococci, group B streptococci, and *Staphylococcus aureus*.* Examination and culture of cholecystectomy specimens from patients with acalculous cholecystitis have revealed positive cultures for *Helicobacter* spp. and *Campylobacter jejuni*. Associations with viral disease include CMV, mumps virus, Epstein-Barr virus, and hepatitis A virus.† Acalculous cholecystitis has been associated with *Plasmodium falciparum* infections (malaria).[62,160,220,228,286] In immunosuppressed hosts, acalculous cholecystitis also has been described in fungal infections with *Candida* spp. or *Aspergillus* spp. or in parasitic infections with *Giardia lamblia* and *Cryptosporidium parvum*.[181]

Noninfectious systemic diseases associated with acalculous cholecystitis or hydrops include neoplastic disease (i.e., leukemia), Henoch-Schönlein purpura, lupus erythematosus, and Kawasaki disease.[33,108,164,248] Table 48-5 includes several conditions with which acalculous cholecystitis has been reported.‡

Clinical presentation is similar to that of patients with calculous disease, with right upper quadrant pain, nausea, vomiting, anorexia, and fever being the most common features. Leukocytosis, jaundice, or a palpable right upper quadrant mass also may be present.[266] The most common setting for acalculous disease is in critically ill or chronically ill patients with concurrent acute or chronic symptoms. A high degree of clinical suspicion is crucial in making the diagnosis in these populations because often the findings suggestive of cholecystitis are obscured by the patient's systemic disease. The most common sonographic finding is a thickened gallbladder wall and a possible sonographic Murphy sign. Gallbladder distention, sludge, or pericholecystic fluid also may be found on transabdominal ultrasonography.[114] In addition to ultrasound, the HIDA scan is an important tool in the evaluation of acalculous cholecystitis. Failure to visualize the gallbladder on scintigraphy and a low ejection fraction in response to a cholecystokinin analog are suggestive of acalculous disease.[163,179,200,290]

CHAPTER 49

Pyogenic Liver Abscess

Sheldon L. Kaplan

Pyogenic liver abscesses are encountered infrequently in healthy children and generally have been reported more commonly in the compromised pediatric host. The rarity of liver abscesses may be explained partly by the rich blood supply, unique architecture, and extensive reticuloendothelial system of the liver, all of which present an effective barrier against bacterial invasion.

The precise incidence of pyogenic liver abscesses in children is unknown. Adult patients with hepatic abscesses constitute approximately 8 to 20/100,000 admissions; a 0.29 to 0.57 percent incidence of liver abscesses has been found in autopsies of adult patients.[11,50] In an early large series of liver abscesses in children, Dehner and Kissane[10] reported a 0.38 percent incidence at autopsy in patients younger than 15 years old; 11 of 27 (41%) patients were younger than 2 years, and 18 of 27 (67%) patients were younger than 6 years. In a review of admissions to Milwaukee Children's Hospital, Chusid[9] found 5 children (4 of whom were <6 months old) with at least one hepatic abscess, and estimated an incidence of 3 cases/100,000 admissions. Pineiro-Carrero and Andres[45] estimated an incidence of approximately 25 cases/100,000 admissions in their pediatric population (11 patients >14 years old). Pyogenic liver abscess in children is encountered more frequently in developing countries than in developed countries.[52] In Taiwan the overall incidence of pyogenic liver abscesses increased from 11.2/100,000 population in 1996 to 17.6/100,000 in 2004.[57]

PATHOGENESIS

Bacteria can establish an inflammatory focus in the liver by four major routes. Direct extension from contiguous structures is the most common mode in adults, accounting for up to 60 percent of hepatic abscesses in adults.[7,25,46,50] Biliary tract infection (cholangitis, cholecystitis), pancreatitis, and penetrating gastric or duodenal ulcer are examples of diseases associated with liver abscesses caused by extension from a contiguous focus of infection. In a review of this problem at St. Louis Children's Hospital, 3 of 27 children (11%) were considered to have a liver abscess secondary to inflammation of contiguous organs.[10] Although biliary tract disease occurs infrequently in children, ascending cholangitis is a particularly frequent complication of the hepatic portoenterostomy procedure for congenital biliary atresia and may lead to infections of the liver in such patients.[14,49] Liver abscesses also may develop as a complication of liver transplantation, especially if technical problems related to vascular supply or biliary drainage develop.[31]

The portal system is the second most common route by which bacteria may reach the liver in adults; 6 to 27 percent of liver abscesses in adults derive from this source.[25,33,50] In newborns, solitary liver abscesses, especially abscesses caused by gram-negative organisms, have complicated the use of umbilical vein catheterization or have been secondary to omphalitis.[6] Prematurity and necrotizing enterocolitis also are important predisposing conditions.[13]

Portal vein inflammation and bacteremia can be associated with infections within the abdominal cavity. Appendicitis, diverticulitis, perirectal abscesses, regional enteritis, ulcerative colitis, and omphalitis are possible sources of portal vein sepsis.[10] A pyogenic liver abscess may be an unusual complication of an ingested foreign body, with subsequent development of portal venous bacteremia.[39] Since antibiotics have been available, portal

vein inflammation and pyelophlebitis have become less common sources of hepatic infection in children.

Systemic bacteremia with hematogenous spread of bacteria to the liver through the hepatic artery seems to be the most common source of liver abscess in children, but it is implicated in less than 20 percent of adult patients. In the St. Louis series, the systemic hematogenous route was responsible for 21 of 27 (78%) cases of liver abscesses.[10] Of 13 patients encountered after 1940, 7 had bacteremia associated with leukemia. Anaerobic bacteremia associated with retropharyngeal or peritonsillar abscesses presumably has preceded development of anaerobic liver abscesses in several children.[8] Likewise, liver abscesses in neonates may be preceded by a systemic bacteremia without evidence of portal or biliary tract involvement.[36]

Liver abscesses occur more frequently in compromised pediatric hosts, especially those with chronic granulomatous disease, than in healthy children.[26] In a registry of 368 patients with chronic granulomatous disease from the United States, a liver abscess occurred in 27 percent of patients.[60] Over the course of 10 years, 15 children were diagnosed with pyogenic liver abscess in a large referral center for pediatric liver disease in the United Kingdom.[37] Three children (20%) had chronic granulomatous disease. In addition to functional disorders of phagocytes, chronic neutropenia predisposes to the development of liver abscesses.[44] Wintch and colleagues[61] noted that 5 of 10 children with hepatic abscesses in their institution had an underlying defect in host defense. Primary hemochromatosis predisposes to multiple liver abscesses caused by *Yersinia enterocolitica* in particular.[58] Pyogenic liver abscesses also are associated with Papillon-Lefèvre syndrome, a rare autosomal recessive disease characterized by palmoplantar keratoderma and periodontitis.[1]

Penetrating and nonpenetrating trauma to the liver may lead to liver abscesses, presumably caused by bacterial proliferation within small collections of blood and bile that result from the trauma. Hepatic abscess may be a rare complication of ventriculoperitoneal shunts after penetration of a peritoneal catheter into the liver.[23,40] This mode of infection has been reported in several children.[22] Liver abscess also is a complication of percutaneous liver biopsy.[16]

Unexplained or cryptogenic hepatic abscesses are encountered in most series and accounted for 40 to 50 percent of cases in many series.[25] Lee and Block[34] have proposed that these cryptogenic liver abscesses "originate from anaerobic bacterial invasion of hepatic infarcts." This theory is supported by reports that describe pyogenic liver abscesses as a complication of hepatic infarction in patients with sickle-cell anemia.[53] Normal gastrointestinal bacterial flora were isolated from 9 of 11 patients with liver abscesses at the Mayo Clinic. This finding suggested to Lazarchick and associates[33] that unrecognized intra-abdominal collections of pus were responsible. Although the reasons are unclear, diabetes mellitus also predisposes to the development of liver abscesses.[22,46,55] Nematode infection with larvae migrating through the liver is thought to be another predisposing factor for the development of pyogenic abscesses in children. The larvae induce liver granulomata that trap bacteria, leading to formation of an abscess.[43] In one study from Brazil, positive serology for *Toxocara canis* was significantly more frequent for patients with pyogenic liver abscess (10/16) than for the 32 age-matched controls (4/32).[48]

Biliary tract disease generally predisposes to the development of multiple liver abscesses. In contrast, blunt trauma to the liver or portal system inflammation most commonly predispose to a single abscess. In neonates, liver abscesses may be solitary or multiple because of systemic bacteria.[36,38] Solitary abscesses are the most common findings in the right lobe of the liver.[33]

Hepatic and splenic abscesses caused by *Candida* spp. are well described in patients with cancer.[54] Multiple abscesses are typical findings. These organs presumably are infected hematogenously, usually when the host is neutropenic.

MICROBIOLOGY

Gram-negative organisms have been the predominant isolates from liver abscesses in adults. *Escherichia coli* and *Klebsiella*, *Aerobacter*, *Pseudomonas*, and *Proteus* spp. have been implicated most frequently. *Klebsiella* spp. were the most common organism isolated from children with pyogenic liver abscess in Taiwan.[56] *Klebsiella* spp. also predominated in Taiwan overall and in adult Asian patients in a report from New York.[47,57] Anaerobic organisms also are important; anaerobic organisms were recovered from 45 percent of patients with liver abscesses in the University of California, Los Angeles series.[51]

In contrast to the adult experience, Dehner and Kissane[10] reported that 33 percent of liver abscesses in children were caused by *Staphylococcus aureus*, whereas gram-negative organisms were found in only 32 percent. Two or more organisms were recovered from liver abscesses in 52 percent of children. In a review of 96 children (no neonates) with pyogenic liver abscesses, *S. aureus*, gram-negative enteric organizations, and anaerobes were the organisms isolated most commonly, in that order.[29] *S. aureus* is the most common isolate that causes pyogenic liver abscess in patients with chronic granulomatous disease. In neonates, gram-negative enteric organisms are isolated most commonly. Anaerobes, particularly *Fusobacterium necrophorum*, have been isolated from liver abscesses in children without underlying disease.[15] Fungi, particularly *Candida albicans*, have been associated with liver abscesses in children with leukemia and neutropenia who have received parenteral hyperalimentation.[3] Liver or splenic abscesses also may be an unusual complication of brucellosis.[59] Human rotavirus–like particles were identified in the material aspirated from a liver abscess, but they were considered a secondary phenomenon and not the primary etiology of the liver abscess.[19]

CLINICAL MANIFESTATIONS

The clinical manifestations of pyogenic liver abscesses are nonspecific. A high index of suspicion and an

awareness of this illness are necessary to establish the diagnosis. A history of preceding abdominal surgery or trauma is helpful when present, as is the knowledge that the host's response to infection is compromised.

Fever, nausea, vomiting, anorexia, weakness, and malaise are prominent symptoms that may last several weeks. Abdominal or pleuritic pain, weight loss, and diarrhea are less common manifestations. A history of abdominal pain and fever of unknown origin in an otherwise healthy child suggests the diagnosis of pyogenic liver abscess.[28] In contrast, fever often is not observed in neonates.[13] Patients with a macroscopic or single abscess frequently experience a subacute to chronic course. In contrast, patients with multiple abscesses generally experience a more acute febrile illness.

Hepatomegaly occurs in 40 to 80 percent of patients; abdominal tenderness occurs less frequently. Right upper quadrant tenderness or even a mass may be subtle and not appreciated, unless the physician specifically and carefully examines this region. Other physical findings include jaundice (generally associated with biliary tract disease and not liver abscesses), abdominal distention, and evidence of pleuropulmonary involvement (i.e., elevated or fixed hemidiaphragm, rales, and pleural effusion).

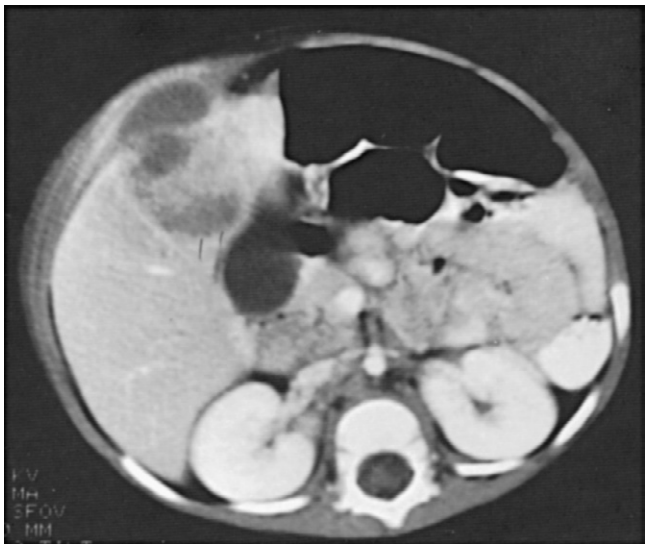

FIGURE 49-1 ■ Abdominal computed tomography scan showing a 4- × 5-cm encapsulated, septate, circular mass within the liver. A low-density soft tissue mass is noted in the abdominal wall from apparent extension from the intrahepatic mass.

DIAGNOSIS

Routine laboratory studies are of little help in establishing a diagnosis. Anemia, leukocytosis, and an elevation in C-reactive protein are common findings. Liver function tests generally reflect underlying disease of the liver itself and usually are not caused by the abscess. When abscesses occur secondary to biliary tract obstruction, alkaline phosphatase and bilirubin concentrations generally are elevated. Transaminase concentrations usually are normal to mildly elevated in most cases. A rapidly enlarging, tender liver in a patient with normal transaminase concentrations should alert the clinician to the possibility of liver abscess. Lazarchick and colleagues[33] found that the serum albumin concentration was the most important test with regard to prognosis in adults; 14 of 16 patients with a serum albumin level of less than 2 g/dL died.

Blood cultures are positive more commonly in patients with multiple abscesses than in patients with solitary abscesses. Overall, however, blood cultures usually are sterile in children with pyogenic liver abscess.

More than 50 percent of adult patients have abnormalities on chest radiography. Atelectasis, pulmonary infiltrates, pleural effusion, and elevated or fixed right hemidiaphragm are the most common findings.

Computed tomography (CT) currently provides the most accurate information concerning the size, location, and number of abscesses within the liver parenchyma (Fig. 49-1).[27,32,45] Lesions measuring 1 cm in diameter can be detected by CT. Multiple small abscesses may appear in clusters in a pattern suggesting early coalescence of the abscesses.[24] Liver abscesses appear as areas of low attenuation. The "target" lesions of hepatic candidiasis are not visualized by CT when the patient is neutropenic, and scans may need to be repeated before these characteristic lesions are observed.[54] Structures contiguous with the liver also are shown by CT; this information is important when a surgical approach to drainage is being planned.

Magnetic resonance imaging does not have any major advantages over CT for detecting or characterizing liver abscess but may show characteristic features to distinguish an abscess from other focal liver lesions in selected patients.[2,35] Ultrasonography also is a sensitive technique for detecting liver abscesses, and because it is noninvasive and does not require exposure to radiation, it is recommended for initial evaluation.[30,32] Hepatic angiography defines the vascular anatomy in the area of the liver abscess further and may provide information necessary for surgical management in selected cases. Nuclear medicine techniques rarely are indicated as a diagnostic method if liver abscess is suspected.

TREATMENT

Numerous reports have documented that patients with undiagnosed and untreated liver abscesses generally die and that surgical drainage of the solitary pyogenic liver abscess is the key to successful treatment. The choice of extraserous or transperitoneal open drainage or percutaneous closed aspiration depends on the location and size of the abscess and the experience and preference of the surgeon.[18,25,42,50]

Numerous groups have described percutaneous catheter drainage of liver abscesses in adults.[4,5,17,30] Percutaneous drainage of liver abscesses in children should be considered as the initial approach to drainage of such abscesses, especially in the right lobe of the liver.[12,45]

A catheter is placed into the cavity under CT or ultrasound guidance; material is aspirated, and, when an

abscess is documented, a draining catheter is placed. The cavity can be irrigated with saline initially. Criteria for the selection of patients for percutaneous drainage have been established.[17] The optimal route of percutaneous aspiration is directly into the abscess cavity and does not involve any uninfected organs or space. Drainage may proceed for 2 weeks or more or until drainage from the cavity is decreased, the patient is afebrile and improving, and radiography shows that the cavity is becoming smaller.[21] Surgical backup is mandatory when this drainage technique is used because spillage of abscess material into the peritoneal cavity, hemorrhage, and other complications may occur. Generally, percutaneous drainage is not indicated for patients with multiple large abscesses or multiloculated abscesses.[25] Heneghan and associates[20] have proposed that indications for surgical drainage of pyogenic liver abscesses are as follows:

1. No clinical response after 4 to 7 days of drainage via a percutaneous catheter placed into the abscess cavity
2. Multiple large or loculated abscesses
3. Thick-walled abscess with viscous pus
4. Concurrent intra-abdominal surgical pathology

Appropriate antibiotic therapy initially is based on knowledge of the organisms most commonly involved, Gram stain of the purulent material, and culture and susceptibility to antibiotics of the organisms that are recovered. If a hematogenous source of infection is suspected or the host has an immunodeficiency disease, *S. aureus* and streptococci are more likely. Biliary tract disease and blunt trauma are associated more frequently with gram-negative aerobic and anaerobic organisms. A logical antibiotic combination for the initial therapy of children with liver abscesses includes a penicillinase-resistant penicillin, such as nafcillin, plus an aminoglycoside. Vancomycin or clindamycin is selected if strains of *S. aureus* resistant to methicillin are present in the community.

The optimal duration and route of administration of antibiotics for a child with a solitary pyogenic liver abscess that has been drained have not been determined. Generally, 2 to 4 weeks of antibiotic therapy administered parenterally, followed by an appropriate oral antibiotic to complete a minimum 4-week total course, should be adequate. Penicillin, ticarcillin-clavulanate, piperacillin-tazobactam, clindamycin, cefoxitin, or metronidazole is administered for anaerobic isolates, depending on susceptibility. Meropenem is useful for polymicrobial infections, including infections caused by gram-negative aerobic and anaerobic rods or organisms that are multidrug resistant.

Multiple liver abscesses are more difficult to treat because achieving complete surgical drainage usually is impossible. Prolonged antibiotic therapy plus treatment of any underlying illnesses is the keystone to effective management. Duration of treatment can be modified, depending on the evidence for resolution of the abscesses as determined by repeated ultrasound examination or CT.

Fungal liver abscesses are difficult to document by culture of the abscess material and prolonged treatment is required. The reader is referred to Chapter 199 on candidiasis and the Infectious Diseases Society of America Clinical Practice Guidelines for the Management of Candidiasis for details of management.[41]

COMPLICATIONS AND PROGNOSIS

Complications of hepatic abscesses vary and are relatively common. Twenty-eight percent of the patients described by Rubin and associates[50] and 44 percent of the patients studied by Pitt and Zuidema[46] had one or more complications. Possible complications include pleural and pulmonary inflammation, peritonitis, subphrenic or subhepatic abscesses, and hemobilia.[10,48]

Polymicrobial bacteremia, hypoalbuminemia, multiple liver abscesses, or the presence of any complication is associated with increased mortality rates in patients with liver abscesses. Overall mortality rates depend largely on underlying pathologic processes and are difficult to interpret. Mortality figures from more recent reports range from 2.5 to 11 percent in adults.[24,45] In children, the prognosis for pyogenic liver abscess is excellent, generally with a low chance of mortality.[36] An increased awareness and suspicion of liver abscesses, in conjunction with ultrasound or CT of the liver, substantially reduces the mortality rate of this disease.

CHAPTER 50

Reye Syndrome

Eugene S. Hurwitz

A syndrome involving the acute onset of encephalopathy associated with fatty metamorphosis of the liver and occurring primarily in children was described first by Reye and colleagues[10,12] in Australia and by Johnson and associates[9] in the United States. The similarities of these two descriptions in separate countries led to the common designation of this clinicopathologic entity as *Reye-Johnson* or *Reye syndrome*. Reye syndrome occurs most frequently after a viral illness and is characterized by the onset of severe vomiting followed by the development of encephalopathy and hepatic dysfunction. The recognition in the early 1980s that the syndrome is associated with the ingestion of aspirin during the antecedent viral illness led to public awareness of this association, a decline in aspirin use for such illnesses in children, and a dramatic decline in the occurrence of this disease in the United States.[1]

EPIDEMIOLOGY

In the United States, national surveillance for Reye syndrome was conducted first during the 1973 to 1974 nationwide outbreak of influenza B and influenza A (H1N1). Such surveillance led to the recognition of outbreaks of Reye syndrome regionally and nationally that were associated with outbreaks of influenza in these and subsequent years.[3] During the first 5 years of surveillance, 250 to 550 cases were reported nationally—an underestimate because it was based on voluntary reporting.[11] Population-based studies conducted in several geographic locations showed that the average annual incidence of the syndrome was one or two cases per 100,000 children younger than 18 years old. Adults rarely were affected. Case-fatality rates reported through national surveillance, initially 40 percent, declined to 20 to 30 percent in later years when the syndrome was prevalent, although this rate undoubtedly was an overestimate because of the tendency to report more severe and fatal cases through this system.

Between 1980 and 1982, four case-control studies reported an association between Reye syndrome and the ingestion of aspirin during an antecedent respiratory or chickenpox illness.[4,13,14] The results of these studies subsequently were confirmed in the Public Health Service Pilot and Main Studies of Reye Syndrome and Medications.[5-7] In these studies, more than 90 percent of patients with Reye syndrome compared with 40 to 70 percent of controls had received aspirin for the antecedent respiratory or chickenpox illness; reported odds ratios were 11.5 to 40. After these studies were reported, publicity and recommendations from various expert panels, including recommendations issued by the U.S. Food and Drug Administration in 1985, led to a decline in the use of aspirin and a decline in the incidence of Reye syndrome, particularly in the age group that had been affected most—children 5 to 15 years old.[1]

CLINICAL MANIFESTATIONS AND LABORATORY FINDINGS

Reye syndrome is described classically as an illness characterized by the abrupt onset of severe vomiting and progressive encephalopathy in a child who is just recovering from a viral illness, the most common of which are influenza and chickenpox. The onset of these symptoms typically occurs within several days after the onset of the viral illness and commonly during a period when the child seems to be recovering from this illness. In association with severe—often projectile—vomiting, which occurs for a transient period, are progressive encephalopathic changes that may follow stages from delirium through confusion, agitation, and lethargy to coma if untreated.

The definition used by the Centers for Disease Control and Prevention (CDC) and widely adopted for clinical purposes includes (1) evidence of acute encephalopathy manifested by alterations in consciousness and documented, when available, by cerebrospinal fluid with less than 9×10^6/L leukocytes or by biopsy or autopsy evidence of cerebral edema without perivascular or meningeal inflammation in histologic sections of the brain; (2) evidence of liver involvement, including either biopsy or autopsy findings of fatty metamorphosis of the liver if available or, in the absence of such specimens, elevations in liver enzymes (alanine aminotransaminase, aspartate aminotransaminase, or serum ammonia) that typically are more than three times normal levels; and (3) no other more reasonable explanation for the cerebral or hepatic abnormalities. The last requirement emphasizes that Reye syndrome is a diagnosis of exclusion and that every effort should be undertaken to identify other possible causes for the clinical and laboratory abnormalities.

Liver biopsy or autopsy findings are considered characteristic and include panlobular microvesicular fat and mitochondrial abnormalities on electron microscopic examination showing peroxisome swelling and enlarged pleomorphic mitochondria with loss of dense granules. Additional findings include normal bilirubin levels and absence of jaundice. Most patients also have hypoglycemia and a prolonged prothrombin time. The typically

elevated cerebrospinal fluid pressure in patients leads to progressive stages of coma.

Staging criteria for Reye syndrome have been used to define the level of encephalopathy. Patients have been reported with liver involvement, but without evidence of encephalopathy. These patients have been described as having stage 0 encephalopathy and, although they do not meet the CDC criteria for Reye syndrome, are considered to have mild disease. Patients with stage I encephalopathy are difficult to arouse and lethargic, whereas patients with stage II are delirious and combative with some movement. Patients with higher stages of encephalopathy (III to V) cannot be aroused and have progressively deeper stages of coma. These patients have a poor prognosis, with a mortality rate approaching 50 percent for patients admitted with stage III or greater and 90 percent for patients admitted with stage V.

Exclusion of other diseases that may resemble Reye syndrome, such as salicylate toxicity, is essential in patients with symptoms resembling this entity. Intensive laboratory investigations should be undertaken to exclude such disorders. In young children, particularly children younger than 3 years of age, inherited metabolic disorders frequently may mimic Reye syndrome and must be excluded. Such metabolic disorders include disorders of fatty acid oxidation, urea cycle disorders, carnitine transport defects, and organic acidemias. Laboratory studies must be performed for the younger age group to exclude these disorders before a diagnosis of Reye syndrome is made, particularly because some of these disorders can be treated effectively. With the declining incidence of Reye syndrome in the typical age group (5 to 15 years) after virtual elimination of the use of aspirin in children, an increasing number of patients with features of Reye syndrome are in this younger age group and ultimately are found, after careful evaluation, to have one of the many metabolic disorders that mimic this syndrome.

An acute encephalopathy mimicking Reye syndrome was recently noted.[8] This 11-year-old boy's illness was due to *Bacillus cereus* emetic toxin cereulide.

TREATMENT AND PREVENTION

The mainstay of treatment of Reye syndrome is early recognition of disease and supportive care focusing on various measures to control intracranial pressure and electrolyte and other abnormalities. Patients should have glucose levels monitored, and early infusion of glucose is considered by many physicians to improve outcome. Comatose patients should be transferred to tertiary care centers that have experience in caring for such patients and can monitor and treat elevated intracranial pressure. When such measures were undertaken before the decline in incidence of this disease, they were associated with improved outcome and decreased mortality. Other therapeutic measures that have been used include efforts to reduce ammonia levels, such as exchange transfusions, peritoneal dialysis, and total-body washout via cardiopulmonary bypass. With advances in supportive care, the mortality rate declined to 10 to 20 percent in later years before Reye syndrome became extremely rare.

Since the association between Reye syndrome and aspirin has been recognized, aspirin no longer is recommended or used for the treatment of febrile illnesses in children. Alternative antipyretics, including nonsteroidal anti-inflammatory drugs and acetaminophen (Tylenol), have replaced aspirin as the primary therapy for such illnesses. These medications have not been associated with an increased risk for development of Reye syndrome. Children with some disorders, including juvenile rheumatoid arthritis and Kawasaki disease, continue to be given aspirin to treat these disorders. Efforts to reduce the risk for development of Reye syndrome in these children have included influenza vaccination annually and vaccination against chickenpox. Careful monitoring of these children also is necessary to ensure early recognition and treatment of Reye syndrome should it occur.

A large number of over-the-counter aspirin-containing products are available in the United States as well as in other countries.[2] It is often not recognized by parents that these alternative medicine products contain aspirin so that children with respiratory illness may on occasion receive aspirin. Therefore, Reye syndrome may still occasionally occur.

SECTION **VIII**

OTHER INTRA-ABDOMINAL INFECTIONS

CHAPTER 51

Appendicitis and Pelvic Abscess

Thomas L. Kuhls

The ability to diagnose appendicitis accurately in a child continues to be one of the most fundamental skills that a pediatric surgeon has to master, although making the diagnosis often is difficult in young patients. The surgeon ultimately is responsible for deciding whether a child is taken to the operating room for appendectomy; however, a primary care physician often is the first person to evaluate the patient who complains of abdominal pain. Pediatricians with expertise in infectious diseases frequently are involved in the care of children who present with subtle or atypical manifestations of appendicitis, have unusual microorganisms recovered from their appendices, or have complications as a result of appendiceal rupture, such as the development of wound infections, sepsis, peritonitis, intra-abdominal abscesses, and pelvic abscesses.

HISTORY

As early as the 16th century, physicians began describing patients with clinical manifestations suggestive of perforated appendicitis. Until the late 1800s, the inflammatory process was called *typhlitis* or *perityphlitis* because the illness was thought to originate from the cecum. In 1886, Reginald Fitz recognized that the source of the inflammation was the appendix and suggested that a laparotomy be performed early in the course of the illness.[63] Shortly afterward, Charles McBurney reported that in patients with appendicitis, tenderness is greatest 2 inches from the anterior iliac spine on a line drawn to the umbilicus.[129] Despite intensive research and refinement of our understanding of appendicitis during the past century, the rates of removing nondiseased appendices or finding already perforated appendices at laparotomy both remained at about 20 percent until more recently when ultrasound and computed tomography (CT) examinations have been commonly used in children with suspected appendicitis.

Despite the continued difficulties in diagnosing appendicitis, the mortality rate from appendicitis has greatly decreased since Fitz reported a 40 percent operative mortality rate. In 1936, Bancroft and Skoluda reported a mortality rate of 8 percent and a complication rate of 11 percent for appendicitis, most likely because of the availabilities of general anesthesia and better aseptic surgical techniques.[23] The second major improvement in outcome occurred in the 1940s, when sulfonamides and banked blood became widely available.[127] In the 1970s, anaerobes such as *Bacteroides fragilis* were found to cause postoperative infections frequently in patients with appendicitis, and treating these microorganisms was found to reduce further the rate of postoperative complications.[116] Currently, death from appendicitis is a rare occurrence in the United States.

EPIDEMIOLOGY

Reported incidences of acute appendicitis vary widely, depending on where the studies were performed and what methodologies were used. The consensus is that the number of cases of acute appendicitis has been decreasing during the past few decades.[96,130] Investigators have estimated that more than 70,000 children are diagnosed with appendicitis each year in the United States.[80] In 1997, appendicitis-related hospitalizations accounted for 0.6 percent of all hospitalizations in the United States, resulting in approximately 1 million hospital days and $3 billion in hospital charges.[47] Although appendicitis occurs in all age groups, the highest incidence occurs during the second decade of life.[3,123] Appendicitis is an uncommon event in children younger than 5 years of age and occurs extremely rarely in infants younger than 6 months old. Patients with acquired immunodeficiency syndrome (AIDS) may have a higher incidence of appendicitis than does the normal population.[108]

Numerous studies have demonstrated that the peak rates of appendicitis occur during the summer months, whereas the lowest rates occur during the winter months.[3,123] An Italian study found a higher rate of pediatric appendicitis in the winter, whereas appendicitis in adults was observed more frequently during the summer.[68] The reasons for these seasonal patterns are unknown, but changes in diet and exposure to allergens have been suggested as explanations.[123] Also, enteric infections occur most frequently during the summer and may play a role in increasing the incidence of appendicitis during this particular season.

Most studies show a modest increase in incidence of appendicitis in males compared with females.[3,123] An estimated lifetime risk for developing appendicitis is 8.6 percent for males and 6.7 percent for females.[3] In a study of acute appendicitis in California, the rate of appendicitis in whites was twice that of blacks and Asians.[123] More recently, Hispanics were shown to have the highest rate of appendicitis-related hospitalizations in the United States.[47] Whether the reported racial differences are due to errors of measurement, sociodemographic factors, environmental factors, factors related to body constitution, or genetic factors remains unknown. Children with appendicitis more frequently have a history of having family members who previously have had appendicitis,

suggesting that genetic background plays a role in the susceptibility to appendicitis.[62] From twin studies, less genetic susceptibility was found in males compared with females.[19] Previous breast-feeding, decreased dietary fiber, ingestion of refined carbohydrates, and atopy have all been suggested to increase the risk for developing appendicitis.[77,155]

Rates of perforation when children are diagnosed with appendicitis are significantly higher in Asian, Hispanic, and black children compared with non-Hispanic white children.[143,156,187] Similarly, children without health insurance or Medicaid have rates of perforation higher than those of children with private health insurance.[156,186] Researchers have suggested that the pediatric rupture rate is a good candidate for inclusion in the National Healthcare Disparities Report.[88] Already, studies have found no differences in perforation rates based on socioeconomic status, showing improved access to early medical care in communities and health systems.[113] Higher perforation rates have been observed in obese individuals and tobacco smokers.[20]

PATHOPHYSIOLOGY

The initial event in the development of most cases of appendicitis is thought to be obstruction of the appendiceal lumen. Microorganisms rarely invade the appendiceal mucosa and initiate the inflammatory process. Appendiceal obstruction can be caused by inspissated feces (fecalith), hypertrophied lymphoid tissue that develops during a systemic viral infection or bacterial enterocolitis, parasitic infestation, appendiceal wall hemorrhage associated with anaphylactic purpura, inspissated barium, or ingested seeds. Continued production of mucus by the appendiceal mucosa distal to the obstruction causes the appendix to distend. Vascular congestion and ischemia occur as the increased intraluminal pressure of the appendix becomes greater than the venous pressure, and edema develops as lymphatic flow becomes obstructed.

Stasis of intestinal flow and intestinal ischemia allow the microorganisms in the appendix to invade the tissues, enhancing the already developing inflammatory response. Bacteria then may translocate across the appendiceal wall and reach the peritoneal cavity.[24] If the process is severe and arteriolar blood flow to the appendix is obstructed, transmural infarction occurs and the appendix ruptures. Microorganisms are liberated into the peritoneal cavity, causing generalized peritonitis and formation of an abscess. Animal studies have suggested that synergism occurring between enteric aerobes, such as *Escherichia coli*, and anaerobes, such as *B. fragilis*, is important in the development of intra-abdominal and pelvic abscesses after perforation.[71] An association between the development of an abscess after appendiceal perforation and the presence of *Streptococcus anginosus* (formerly *S. milleri*) also apparently exists.[76]

As the appendix distends in the early stages of appendicitis, the visceral afferent autonomic nerves that enter the spinal cord at T8 to T10 are stimulated, referring the pain to the epigastric and periumbilical areas of the abdomen. When the inflammatory response reaches the serosal surface of the appendix, the parietal peritoneum is stimulated and the pain intensifies in the right lower quadrant. If perforation occurs, the peritoneal inflammatory response causes more generalized abdominal tenderness.

Although appendiceal obstruction may play an important role in the early stages of most cases of appendicitis, not all obstructed appendices become inflamed. Ten percent of normal appendices removed during abdominal surgical procedures contain inspissated fecal material. Also, children may develop recurrent, crampy abdominal pain, possibly from intermittent appendiceal obstruction.

The classic description of the pathophysiology of appendicitis does not easily explain many epidemiologic features of this disease, including its higher incidence in males and certain races. The amount and reactivity of the lymphoid tissue in the wall of the appendix have been suggested to be key determinants to the development of appendicitis. The amount of lymphoid tissue in the appendix is greatest during adolescence when the disease process is most prevalent and the amount most likely is controlled genetically.

In a case-control study from Italy, prolonged breast-feeding during infancy was associated with a decreased risk for developing acute appendicitis later in life.[155] The investigators hypothesized that breast-feeding may have decreased the amount of stimulation to intestinal lymphocytes by microbial and food antigens early in life, so that appendiceal lymphoid tissues were less reactive to antigenic challenge during adolescence and adulthood. Appendicitis may be observed less frequently during infancy and the neonatal period because the appendix is more funnel shaped, the diet is primarily liquid, recumbent posture is maintained for prolonged periods, and gastrointestinal and respiratory tract infections develop less frequently during this time.

CLINICAL MANIFESTATIONS

In school-aged children and adolescents with appendicitis, the median duration of symptoms before the time of hospital admission is 24 to 28 hours.[162] Pain in the right iliac fossa is the most common sign of appendicitis, occurring in 88 to 99 percent of patients.[162,167] Pain shifts from the periumbilical area to the right lower quadrant of the abdomen in approximately two thirds of children with appendicitis. In three fourths of children, the pain worsens during movement. The characteristics of the abdominal pain do not always predict accurately which children have appendicitis. Of children found to have mesenteric adenitis at laparotomy, 25 percent report a shift in their abdominal pain to the right iliac fossa and 33 percent experience worsening of their pain during movement.[162]

Nausea and vomiting are found in 86 to 96 percent of children with appendicitis.[162,167] Vomiting usually occurs after the onset of abdominal pain but may precede pain in nearly 20 percent of cases. If only nausea or vomiting is present, it is less likely the child has appendicitis.[162] Anorexia occurs less commonly in children than in adults, occurring in 47 to 91 percent of cases of appendicitis. Because 50 percent of children found to have normal appendices at surgery complain of anorexia,

differentiating appendicitis from other causes of right iliac fossa pain is not always helpful. Similarly, complaints of diarrhea (9% to 16%), constipation (5% to 28%), and dysuria (7%) occasionally can be elicited from children with appendicitis.[162,170]

Fever is a useful diagnostic sign of appendicitis in children with right lower quadrant abdominal pain.[38,58] A temperature greater than 37.5 °C (99.5 °F) is found in 68 to 96 percent of cases. Very high temperatures (>39 °C [102.2 °F]) suggest that perforation already has occurred or that another intra-abdominal process is present. Rarely, children present with erythema and tenderness of the scrotum as the only manifestation of acute appendicitis.[227]

During the physical examination, the child frequently lies quietly on the examination table with the right hip flexed. Tenderness in the right iliac fossa is the most sensitive sign of appendicitis, occurring in 93 to 100 percent of cases of appendicitis.[162,167] The psoas muscle may become irritated from the inflamed appendix, causing the child to feel increased pain when the right hip is flexed actively. Likewise, if the obturator internus muscle is involved, pain is elicited when the flexed thigh is rotated internally. Guarding is found in 80 to 91 percent of cases of appendicitis, compared with 50 percent of cases of mesenteric adenitis and 8 percent of cases of nonspecific abdominal pain.[162] Similarly, rebound tenderness is found in 56 to 83 percent of cases of appendicitis, 33 percent of cases of acute mesenteric adenitis, and 1 percent of cases of nonspecific abdominal pain; its presence triples the odds of the child having appendicitis.[38,58,162]

The development of diffuse abdominal tenderness and the absence of bowel sounds usually indicate perforation. Extremely hyperactive bowel sounds suggest that the patient may not have appendicitis. Occasionally, a mass can be palpated in the right lower quadrant of the abdomen in children with appendicitis who are relaxed or well sedated. Rectal tenderness is present more commonly in children with appendicitis (44% to 68%) than in children with other causes of abdominal pain (12%); however, findings during the rectal examination seldom alter the clinical decision of the surgeon.[162]

In preschool-aged children, the diagnosis of appendicitis is more difficult to establish because of the inability of young children to express their symptoms and because they often do not cooperate during the physical examination.[221,222] Young children with appendicitis are often seen early in the course of their symptoms and are prescribed antibiotics, antihistamines, or antipyretics. By the time one realizes that the child has appendicitis, the appendix usually is perforated (50% to 90%).[221,222] In contrast to older children, vomiting is the initial symptom of appendicitis most frequently observed and abdominal pain may be absent or may never localize in the right iliac fossa.[162] Sleep disturbances, irritability, restlessness, and crying are common manifestations of appendicitis in this age group. The preschool-aged child is more likely to have a palpable inflammatory mass at presentation.

During the newborn period, appendicitis is an extremely rare occurrence, although most cases are found when prematurity exists.[92] Symptoms of neonatal appendicitis include abdominal distention; vomiting; irritability; diarrhea; erythema, edema, or cellulitis of the abdominal wall; gastrointestinal hemorrhage; abdominal rigidity; lethargy; and jaundice. Usually, the symptoms of neonatal appendicitis are indistinguishable from those of necrotizing enterocolitis. Underlying conditions such as total colonic Hirschsprung disease, meconium plugs, esophageal atresia, or hernias may predispose the neonate to develop this condition.

In children who are undergoing chemotherapy for leukemia, acute appendicitis may present as only vague abdominal pain, abdominal distention, lack of abdominal guarding, fever, dehydration, diarrhea, or unusual symptoms such as gastrointestinal bleeding.[12] Symptoms of appendicitis in immunocompromised patients may be identical to those of typhlitis.

The differential diagnosis of acute abdominal pain in children is extensive. Table 51-1 includes conditions that can manifest as symptoms suggestive of acute appendicitis.

DIAGNOSIS

The diagnosis of acute appendicitis should be established without laboratory studies when a child complains of abdominal tenderness in the right lower quadrant that initially started in the periumbilical area, has fever, develops nausea and vomiting, and has rebound tenderness in the right lower quadrant with guarding during an abdominal examination. The child should be taken to the operating room for an appendectomy as soon as possible before perforation occurs.[101] Most children do not have all of the classic clinical manifestations of appendicitis; thus, a great emphasis has been placed on using various laboratory tests to help clinicians diagnose the disease accurately.[106] Similarly, patients who have received prior oral antibiotics may have milder symptoms and signs of classic appendicitis, necessitating further diagnostic studies.[61]

For decades, physicians have valued peripheral blood leukocyte counts, neutrophil counts, C-reactive protein concentrations, and erythrocyte sedimentation rates to help them distinguish appendicitis from other causes of abdominal pain. When properly evaluated, these tests have been found to be too insensitive to use as reliable tools for diagnosing appendicitis.[26,55,169] Normal results do not rule out the possibility that the child has appendicitis, although these tests help to confirm a physician's suspicions when results are positive. When the nonspecific tests are elevated, often perforation or abscess formation has occurred.[8,150] Similarly, hyperbilirubinemia found in children with symptoms of appendicitis is a sign of probable perforation.[174] Certain groups of patients commonly have normal leukocyte counts despite having acute appendicitis. Black patients with acute appendicitis frequently do not develop leukocytosis.[87] Patients with AIDS who develop appendicitis also frequently do not have elevated white blood cell counts.[34]

Routine radiographic studies for the diagnosis of appendicitis in children no longer are suggested. Radiographs of the abdomen are not sensitive nor specific enough for diagnosing childhood appendicitis. Abnormalities described in association with acute appendicitis include an abnormal bowel gas pattern, a mass, a fecalith,

Porphyria
Rocky Mountain spotted fever
Sickle-cell disease
Tuberculosis

and obliteration of normal fat planes in the right lower quadrant. Gas in the appendiceal lumen is thought to be diagnostic of acute appendicitis but may occur rarely in its absence. Most children do not have radiographic findings of appendicitis or findings are nonspecific.

Graded compression ultrasonography has become the diagnostic procedure of choice in some institutions when evaluating a patient with possible appendicitis.[152] A transducer is used to apply gradual pressure to the abdomen. The technician must ensure that all gas and fluid contents from the loops of bowel are expressed for the examination to be adequate. A noncompressible, enlarged (>6 mm in diameter in adolescents) appendix or a fecalith is the major criterion used for diagnosing appendicitis by ultrasonography. Interruption in the continuity of the echogenic submucosa suggests necrosis of the appendiceal wall and impending perforation. An echogenic periappendiceal mass indicates inflammation of the mesenteric or omental fat. Loculated or generalized fluid collections suggest that perforation already has occurred.

Because graded compression ultrasonography is highly operator dependent, a meta-analysis has demonstrated that the procedure is 88 percent sensitive and 94 percent specific in diagnosing acute appendicitis in children.[52] False-positive ultrasound results occur in obese patients who have noncompressible appendices because of overlying fat and in children who have inflamed appendices caused by Crohn disease, ulcerative colitis, or adjacent salpingitis. False-negative results occur if retrocecally located appendices are not visualized properly; if the cecum is filled with gas or feces and is not compressed adequately; or if perforation has occurred, allowing the appendix to be compressible. In one study, a noncompressible appendix was identified in only 38 percent of pediatric patients with perforated appendicitis, thus rendering the other ultrasound findings of appendicitis important in diagnosing the disease.[158] The examination should be directed to diagnose other causes of abdominal pain that can mimic appendicitis when a normal appendix is found during the evaluation.

The advantages of using ultrasonography over CT are that it is relatively inexpensive, is safe, does not require sedation, lacks radiation exposure, and is widely available. It is especially useful in adolescent girls with abdominal pain because gynecologic causes of the pain can be evaluated easily at the time of appendiceal examination.

Most North American pediatric surgeons prefer CT over ultrasonography as the diagnostic procedure of choice for appendicitis.[152] High-resolution CT has higher sensitivity (94%) and similar specificity (95%) than ultrasonography in diagnosing appendicitis, and it is less operator dependent.[52] Intravenous contrast agents and high-resolution, thin-section scanning techniques must be used to visualize the appendix adequately. An enlarged appendix with a circumferentially and symmetrically thickened bowel wall is the most common CT finding in appendicitis. Periappendiceal inflammatory reaction or fluid collections may be identified. If the appendix is not well visualized, the presence of a fecalith, along with pericecal inflammatory changes, strongly suggests appendicitis. Fecaliths can be visualized in normal appendices by CT, however, and are of no clinical significance unless other inflammatory changes are present.

Helical or multidetector CT techniques using rectal or no contrast have been shown to be very accurate in diagnosing appendicitis.[54,122,197] By using a focused right lower quadrant approach, helical CT may be completed more rapidly. Because of the high accuracy rates in diagnosing appendicitis, some physicians have suggested that

all children with suspected disease should have CT.[102] In most community hospitals and medical centers, waiting for a CT scan may delay a surgical consultation and increase the rate of perforation before surgery.[114] Also, CT is expensive and uses significant amounts of ionizing radiation in children who have greater radiosensitivity of organs and tissues compared with adults. Some medical centers have implemented protocols that initially use ultrasonography as the first diagnostic procedure for possible appendicitis and only use CT when the ultrasound results are equivocal to reduce cost and radiation exposure.[152]

Whether the increasing use of ultrasonography and CT to diagnose appendicitis in children has decreased the misdiagnosis of the disease and subsequent negative appendectomy rate in hospitals is unclear.[65,93,126,229] In a single study, the misdiagnosis rate was lower in hospitals that perform frequent pediatric appendectomies.[186] Most children with appendicitis, however, have surgery in hospitals other than children's hospitals.[45]

Radiolabeled autologous leukocyte scans also have been used to diagnose appendicitis in children; however, this modality should be reserved for atypical presentations of disease when localizing signs are not present.[81] Magnetic resonance imaging may be considered in patients with nondiagnostic ultrasound tests and concerns about radiation exposure.[105]

MICROBIOLOGY

Numerous microorganisms have been implicated as a cause of acute appendicitis; however, considerable debate has ensued as to whether simply isolating an organism from the appendiceal lumen is sufficient proof to define causation (Table 51-2).[2]

TABLE 51-2 **Microorganisms Associated with Acute Appendicitis in Children**

Anaerobes
Bacteroides spp.
Bilophila wadsworthia
Catabacter hongkongensis
Clostridium spp., including *C. difficile*
Fusobacterium spp.
Peptostreptococcus spp.
Pigmented bile-resistant, gram-negative rods
Turicibacter sanguinis

Enteric Aerobes and Facultative Anaerobes
Aeromonas spp.
Campylobacter spp.
Citrobacter spp.
Enterobacter spp.
Enterococcus spp.
Escherichia coli
Klebsiella spp.
Morganella morganii
Proteus spp.
Providencia rettgeri
Salmonella spp.
Shigella spp.
Streptococcus anginosus (formerly *milleri*) group
Yersinia species

Other Bacteria
Actinomyces spp.
Atypical mycobacteria (in patients with AIDS)
Chromobacterium violaceum
Corynebacterium appendicis
Eikenella corrodens
Haemophilus spp.
Ehrlichia chaffeensis
Kluyvera ascorbata
Pasteurella multocida
Pseudomonas spp.
Staphylococcus spp.
Streptococcus pneumoniae
Streptococcus pyogenes

Parasites
Angiostrongylus costaricensis
Anisakis spp.
Ascaris lumbricoides
Balantidium coli
Cryptosporidium parvum
Entamoeba histolytica
Enterobius vermicularis
Schistosoma spp.
Strongyloides stercoralis
Taenia spp.
Trichuris trichiura

Viruses
Adenoviruses
Coxsackievirus B
Cytomegalovirus
Epstein-Barr virus
Measles virus

Fungi
Candida albicans
Coccidioides immitis
Mucor spp.
Histoplasma capsulatum

Bacteria

In most cases of appendicitis, bacteria do not appear to be involved directly in the initial stages of the inflammatory process. Microorganisms that normally inhabit the appendix are liberated into the peritoneal cavity when appendiceal perforation occurs or when translocation through the inflamed tissues is present, and polymicrobial infections develop as a complication of the disease process.[27,204] In a study of 30 adolescents and adults with nonperforated and perforated appendicitis, 223 different anaerobes and 82 aerobes were recovered from cultures of their appendiceal tissues, peritoneal fluid, and contents of abscesses.[27] An average of 10 different organisms were isolated per specimen collected.

In most microbiologic studies of appendiceal tissues and peritoneal fluid specimens from patients with appendicitis, *B. fragilis* is the strict anaerobe isolated most frequently, occurring in more than 70 percent of patients.[27,164] Other anaerobes that are isolated frequently include *Bacteroides* spp., *Bilophila wadsworthia*, *Peptostreptococcus* spp., *Fusobacterium* spp., and *Clostridium* spp.[210,225] A gram-negative anaerobic rod that develops a pigment in culture and is bile resistant also has been identified frequently.[163,164] Anaerobes such as *Turicibacter sanguinis* and *Catabacter hongkongensis* continue to be newly described from patients with appendicitis.[33,109] Rarely, acute appendicitis has been seen in the setting of *Clostridium difficile* colitis, although the role of the anaerobe's toxins in causing the appendiceal inflammation is unknown.[36]

E. coli is the aerobic or facultative anaerobic bacteria isolated most frequently from children with appendicitis. *E. coli* is found in more than 75 percent of patients.[27,164] Researchers have suggested that certain *E. coli* strains with type 1C fimbriae may contribute to the development of appendiceal inflammation.[178] Enterohemorrhagic *E. coli* O157:H7 and O111:H have been isolated infrequently from the stools and peritoneal fluid of children with appendicitis.[208,215]

Viridans streptococci of the *S. anginosus group* can be found in more than 60 percent of cultures from children with appendicitis.[89,164] Group D streptococci are isolated in 20 to 30 percent of patients with appendicitis, whereas *Pseudomonas* spp. are isolated slightly less frequently.[164] Other aerobes or facultative anaerobes that can be isolated from appendiceal tissues, abscesses, or blood include *Citrobacter* spp.; *Klebsiella* spp.; *Enterobacter* spp.; *Proteus* spp.; *Morganella morganii; Providencia rettgeri; Eikenella corrodens;* groups C, F, and G β-hemolytic streptococci; and staphylococci.*

Rarely, encapsulated organisms, such as *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Haemophilus segnis*, and *Aggregatibacter aphrophilus* have been isolated from appendiceal tissues or peritoneal fluid of young children with appendicitis, and often these organisms have been isolated in pure culture.[17,18,134,141] Very rarely, organisms such as *Pasteurella multocida*, *Streptococcus pyogenes*, and *Actinomyces* spp. have been cultured from patients with appendicitis.[56,120,161] *Shigella*, *Salmonella*, *Campylobacter*, *Yersinia*, and *Aeromonas* spp. also have been isolated occasionally from appendiceal tissues or peritoneal fluid of patients with nonperforated and perforated appendicitis; but, again, whether they played a role in the pathogenesis of disease is unknown.* Much more commonly, these organisms cause enterocolitis or mesenteric adenitis, with symptoms mimicking appendicitis.[212]

Appendicitis has occurred during systemic infections caused by *Brucella melitensis* and *Ehrlichia chaffeensis*.[11,182] Rarely, *Kluyvera ascorbata*, *Arcobacter butzleri*, and *Chromobacterium violaceum* have been isolated from individuals with appendicitis, as well as newly described aerobes and facultative anaerobes, such as *Corynebacterium appendicis*.[40,42,111,226]

Rarely, isolated primary tuberculosis can occur in children.[29,159] The progression of disease is usually rapid; thus one should be suspicious when caseating granulomas are observed in histopathologic sections of the appendix.

Adults and children with appendicitis usually are not bacteremic at the time they are diagnosed, especially if the appendix is not perforated. Occasionally, *Klebsiella pneumoniae*, *E. coli*, *B. fragilis*, and *B. wadsworthia* are isolated from the blood of patients with nonperforated appendicitis.[30,171,173] In a review of 1000 children and adults with appendicitis, 10 percent of patients with perforation had positive blood cultures, whereas none of the patients without perforation had bacteremia.[117] A higher rate of bacteremia may occur when laparoscopic surgery is performed because of the air that is forced into the peritoneum, although the clinical significance of the induced bacteremia is unknown.[147]

In immunocompromised patients who develop appendicitis, the microorganisms that are isolated from appendiceal tissues or peritoneal cultures usually are identical to those found in immunocompetent patients. Patients with AIDS who have gastrointestinal *Mycobacterium avium* complex or *Mycobacterium tuberculosis* infections may develop symptoms that mimic appendicitis.[49,214] Atypical mycobacteria have been isolated from an appendiceal abscess from a child with AIDS.[60]

Parasites

Roundworms, such as *Ascaris lumbricoides*, may obstruct the appendiceal lumen occasionally and initiate the cascade of inflammatory events leading to perforated appendicitis.[124,148] Parasites such as *Enterobius vermicularis* can be identified in the lumen of 1 to 12 percent of surgically removed appendices obtained from patients living in highly endemic areas.[14,78] Pinworms have been found more frequently, however, in appendices with no evidence of appendiceal inflammation in some studies, suggesting that pinworms probably are a part of the normal appendiceal flora and do not play a role in the pathogenesis of appendicitis.[172,228] Whether some parasites may cause abdominal pain that mimics the symptoms of appendicitis necessitating surgical intervention remains unclear.

Scattered reports from mostly developing nations describe other worms, including *Taenia* spp., *Anisakis* spp., *Trichuris trichiura*, *Strongyloides stercoralis*, *Schistosoma* spp., and *Angiostrongylus costaricensis*, that have been identified in the lumen of appendices from patients with

*References 53, 79, 91, 160, 164, 204.

*References 25, 28, 39, 98, 110, 119, 135.

appendicitis.[4,15,73,100,142] Similarly, protozoa such as *Balantidium coli*, *Entamoeba histolytica*, and *Cryptosporidium parvum* have been found in inflamed appendices of immunocompromised and immunocompetent patients, but whether they play a role in the pathogenesis of disease is unknown.[10,37,51]

Viruses

The role that viruses play in causing appendicitis also has been debated. One suggestion is that a systemic viral infection may induce hypertrophied lymphoid aggregates that obstruct the appendiceal lumen. In the 1960s, elevated levels of antibodies against group B coxsackieviruses and adenoviruses were found in the sera of some children with appendicitis.[205] A later study, however, could not confirm this finding.[137] Six adolescents with infectious mononucleosis have developed appendicitis, and cytomegalovirus has occasionally been observed in immunodeficient and otherwise healthy patients' inflamed appendices.[95,121,144,203] Other children have had histologic evidence of measles virus or adenovirus infection.[72,190] Because of the rarity of documented simultaneous viral infections and appendicitis, whether these viruses play a major role in the pathogenesis of acute appendicitis is doubtful.

Fungi

Rarely, *Candida albicans* is isolated from inflamed appendices or abscess cultures, but its role in pathogenesis of disease is unknown. Perforation of the appendix from intestinal mucormycosis has occurred in granulocytopenic patients and premature newborns.[145,202] Also, appendicitis has been described in individuals with histoplasmosis and coccidioidomycosis.[107,188]

TREATMENT

Nonperforated Appendicitis

In previously healthy children with signs of acute appendicitis and no clinical evidence of perforation, nasogastric suctioning should be established and imbalances in fluid and electrolyte concentrations should be corrected quickly. The child should be taken to the operating room as soon as possible for appendectomy. Many teaching hospitals now perform appendectomies only during day and evening hours, because of limitations on resident work hours and decreased services available at night. No differences have been noted in perforation rates, lengths of stay, or complication rates in children who are diagnosed with appendicitis at night and given analgesics until a scheduled morning surgery if the delay time is less than 12 hours.[1,7] Morphine can be used to reduce the severity of abdominal pain in children with appendicitis until the child is taken to the operating room and does not impede establishing the diagnosis in children under observation for suggestive symptoms and signs of appendiceal disease. There is no evidence, however, that morphine reduces appendiceal pain compared with placebo.[5,22]

Prophylactic antibiotics given perioperatively decrease the rate of postoperative wound infection, even in noncomplicated cases of childhood appendicitis.[6,183] No consensus exists concerning the appropriate antimicrobial agent or agents that should be used to reduce the complication rate. Although some surgeons continue the antibiotics after surgery, prospective, randomized studies demonstrate that a single perioperative dose of proper antibiotic(s) with antimicrobial activity against *E. coli* and enteric anaerobes is as effective as continuing the antibiotic(s) for 1 to 5 days after surgery.[139,207]

Few data support the routine intraoperative collection of peritoneal fluid or appendiceal cultures in children with nonperforated appendicitis, although 5 to 20 percent of cultures grow enteric aerobes, anaerobes, or both.[69] Immunocompromised patients should undergo intraoperative cultures, including cultures for mycobacteria and cytomegalovirus.

Most pediatric surgeons are now performing laparoscopic appendectomies in children with nonperforated and perforated appendicitis. Advantages of the procedure are a reduction in wound infection, reduction in scarring, less postoperative pain at 24 hours, shorter hospital stay, and earlier return to normal activity, although the procedure must be performed by a surgeon experienced in laparoscopic technique.[118,177,219] The mean total cost of a laparoscopic appendectomy is similar to that of open appendectomy. Meta-analyses have determined that there is increased operative time and a small increase in the risk for developing a postoperative abscess using the laparoscopic technique.[118,177,219] It is unclear whether the newer single incision laparoscopic technique improves outcome compared with conventional multiple-incision laparoscopy.[165,192]

Outside North America, children with nonperforated appendicitis are often treated initially with intravenous fluids and antibiotics. Two thirds of patients may be treated successfully without surgery.[64,213,216] When the child does not clinically improve or a walled-off abscess develops, drainage of the area and appendectomy are performed. If the child responds to conservative management, it is controversial as to whether an interval appendectomy has to be performed 6 to 8 weeks after resolution of the symptoms. Proponents of initial conservative management consider that the complication rate after interval appendectomy is significantly lower than when a procedure is done during the acute stage of disease.

Perforated Appendicitis

Most surgeons advocate early intervention when perforation has occurred to prevent severe complications such as fistula formation, abscess rupture, and death, despite the high chance of developing postoperative complications.[112] Debate ensues as to whether the wound(s) should be closed primarily and whether transperitoneal drains should be placed at the time of surgery.[57] Surgeons are increasingly performing primary closures without drains in children.[59,131] A randomized prospective trial of appendiceal drains in children with perforated appendicitis showed no benefit in using drains compared with primary wound closure.[198] Appendectomy wounds can be closed

with continuous, absorbable sutures even in complicated cases.[153] If incisions are not primarily closed, simple daily wound probing may decrease the incidence of wound infection.[206]

During the surgical procedure, many surgeons irrigate the peritoneal cavity with copious amounts of saline or antibiotics to reduce the quantity of bacteria in the abdomen. To obtain sterile cultures of the lavage fluid, 6 L of lavage fluid per square meter body surface area of the child is required.[149] It is unclear whether the lavage fluid or the addition of antibiotics to the lavage fluid decreases the rate of postoperative complications in children with perforated appendicitis who are receiving systemic antibiotics.[128] Ranitidine or diphenhydramine given to children with perforated appendicitis may increase the risk for developing a postoperative abscess.[194]

Antimicrobial agents should be administered routinely to children when perforation or appendiceal abscess is suggested or discovered during surgery. Antibiotics active against aerobes and anaerobes that normally inhabit the intestinal tract have been effective in treating children with perforated appendicitis. Treatment failures occur most commonly when *B. fragilis* or *Pseudomonas* spp. are isolated from intraoperative cultures and antimicrobial agents without activity against these organisms are used.[83] Controversy continues regarding the value of obtaining routine intraoperative peritoneal cultures in cases of perforated appendicitis, although most studies demonstrate that culture results seldom change the clinical management of patients.[48,69]

The antimicrobial combination of ampicillin, gentamicin, and clindamycin has been the gold standard of therapy since the 1970s. The importance of including ampicillin in the regimen for adequate enterococcal coverage continues to be controversial. Animal studies and clinical trials using antibiotics with poor enterococcal activity have shown that ampicillin probably is not required in the treatment of perforated appendicitis.[71] Because of the increasing problem of ampicillin resistance in enterococci, ampicillin probably should be reserved for the rare child with enterococcal bacteremia or with persistent intra-abdominal infection in which enterococci have been isolated. Some medical centers use metronidazole instead of clindamycin because of its broader activity against enteric anaerobes, whereas other institutions substitute cefotaxime or ceftriaxone for gentamicin.[180,193] In a small study, once-daily dosing of ceftriaxone and metronidazole was comparable in efficacy to standard three-drug therapy in children with perforated appendicitis.[195]

Single-agent antibiotic therapy for perforated appendicitis may offer improvement in terms of pharmacy and hospital costs.[70] Agents that have been shown to be effective in treating children with perforated appendicitis include cefoxitin, imipenem-cilastatin, ticarcillin-clavulanate, piperacillin-tazobactam, ampicillin-sulbactam, meropenem, and ertapenem.* In a few medical centers, nearly 50 percent of *B. fragilis* isolates are resistant to cefoxitin, raising the question as to whether cefoxitin should be used routinely as a single agent in these institutions.[67] Generally, the convenience of monotherapy does not outweigh the potential development of resistance to these broad-spectrum agents. They may be useful in the treatment of appendicitis in children with renal disease or hearing loss when avoiding the use of gentamicin is prudent.

Most patients with perforated appendicitis are treated with intravenous antibiotics for 5 to 10 days after surgery; however, limiting the duration of antibiotic use to 3 days does not lead to higher rates of wound infections or intra-abdominal abscesses in children who are afebrile and eating.[82,189] Efforts have been made to shorten the hospital stay of children with perforated appendicitis. Some institutions have set criteria for hospital discharge and discontinuation of antibiotics, such as absence of fever for 24 hours, ability to eat well, and less than 3 percent band forms on the white blood cell differential.[84] Many surgeons will switch to oral antibiotics at home after 3 to 5 days of intravenous antibiotics in the hospital, although the benefit of adding prolonged oral antibiotics to a 3-day course of intravenous antibiotics has not been shown.[66,200] Providing home single intravenous antimicrobial therapy also can reduce costs and hasten hospital discharge in selected children with perforated appendicitis.[191]

Similar to nonperforated appendicitis, some controversy exists regarding whether immediate appendectomy should be performed on children in whom a palpable mass is associated with their appendicitis or who show evidence of appendiceal rupture with or without abscess formation at the time of presentation.[32,132] Similarly, there is a lack of prospective studies to determine if interval appendectomy is required after successful nonoperative treatment of an appendiceal mass in children.[75] Families do experience more stress when nonoperative management of perforated appendicitis is implemented.[181]

PROGNOSIS AND EARLY COMPLICATIONS

Currently in the United States, the risk of dying of appendicitis is very low. It has been stated that the risk of death from appendicitis should be the risk of death from general anesthesia.[127] The mortality rate is higher in the rare newborn or premature infant who develops appendicitis. Also, factors contributing to the death of children rarely may include delay in establishing diagnosis, inadequate fluid replacement, immunodeficiency, and postoperative vascular or infectious complications.

The most predictive factor of postoperative morbidity occurring from appendicitis is perforation.[166] Age, obesity, duration of the surgical procedure, and nutritional status also are risk factors for the development of complications. Wound infection rates in children who receive perioperative antibiotics should be less than 7 percent; infections generally are caused by the same organisms that are isolated in cultures obtained during the appendectomy.[183,207] Occasionally, children develop peritonitis, intra-abdominal abscesses, psoas abscesses, fistulas, pylophlebitis of the portal vein, scrotal abscesses, empyema, or pneumoperitoneum during the course of treatment of

*References 125, 140, 184, 185, 201, 209, 223.

appendicitis.* Postoperative morbidity rates appear similar in children with nonperforated appendicitis when surgery is performed in teaching institutions compared with community hospitals; however, the rates are higher in children with perforated appendicitis in community hospitals.[115]

CT can be successfully used to detect postoperative abscesses even in the first week after surgery.[13] If complications occur, another surgical procedure often is performed and antibiotic treatment is prolonged. Abscesses may be treated successfully with antibiotics alone and without surgical drainage in stable patients after appendectomy.[50]

PELVIC ABSCESS

The pelvic area is a common site for development of abscesses because it is the most dependent portion of the peritoneal cavity. Pelvic abscesses most commonly occur in children who have had intestinal perforations after appendicitis, have suffered penetrating abdominal or retroperitoneal injury, or have undergone an abdominal surgical procedure. Occasionally, adolescents with pelvic inflammatory disease or Crohn disease develop a pelvic abscess.

In children with perforated appendicitis, a coexisting pelvic abscess often is diagnosed at the time of laparotomy. In patients who recently have had penetrating trauma to the abdomen, have had pelvic inflammatory disease, or have undergone gastrointestinal surgery, a pelvic abscess should be suspected when they have continued fever or complain of abdominal pain despite receiving adequate treatment of the initial disease process. Symptoms may not develop until days to months after therapy is ended. No characteristic physical findings are associated with a pelvic abscess, although abdominal palpation or rectal examination may elicit tenderness or signs of intestinal obstruction may be present.

If a pelvic abscess is suspected, contrast CT evaluation of the pelvis should be completed. The bladder should be filled before the procedure so that it can displace bowel loops from the pelvis, act as an anatomic marker, and act as a standard of fluidity against which an abscess cavity can be compared. Walled-off fluid collections in the pelvis can be identified and sometimes the rectum, sigmoid colon, or bladder is compressed because of mass effect from the abscess cavity. Because most pelvic abscesses develop as complications of intestinal or pelvic infections, enteric aerobes and anaerobes are the organisms most commonly isolated from the abscess cavity. Yeasts rarely cause pelvic abscesses.[211,220] *Actinomyces*-related pelvic abscesses uncommonly are observed.[154] Tuberculous abscesses can develop as a complication of genital tuberculosis.[218]

When a pelvic abscess is identified, antibiotics covering intestinal aerobes and anaerobes, such as clindamycin and gentamicin, should be started, and the abscess contents should be drained. In most situations, reaching the abscess cavity by an anterior approach is difficult. Considerable interest has developed in using CT or ultrasonography to guide percutaneous drainage of pelvic abscesses by transgluteal, transrectal, transparacoccygeal, or transvaginal approaches.[90,146,157,175] Although placement of a transgluteal catheter is easiest, the sciatic nerve and gluteal vessels must be avoided. Also, an increased risk for development of a wound infection may occur because microorganisms may track along the outside of the catheter to the skin. Many surgeons prefer the transrectal approach because it often is the most direct route to the abscess. Transvaginal drainage has been used with good results in young women. Most often, drainage catheters can be removed after 7 to 10 days of treatment.

Abscesses also may develop within the muscles of the pelvic girdle, including the psoas and internal obturator muscles.[179,196] Similar to true pelvic abscesses, they usually cause fever and occasionally abdominal complaints in children. Most children begin to limp, refuse to walk, or complain of pain in the buttocks, thigh, or groin. Often, a suppurative hip infection is suspected initially. A pelvic muscle abscess is usually diagnosed by CT or magnetic resonance imaging. Labeled leukocyte scans sometimes are useful in localizing the infection to within the pelvis, especially when the child has no symptoms other than fever or refusing to walk.

Pelvic muscle abscesses can develop as a complication of Crohn disease or appendicitis; however, they often develop after an episode of bacteremia.[31,176] *Staphylococcus aureus* is the most common cause of a primary pelvic muscle abscess with methicillin-resistant strains being increasingly identified.[151,179] *S. pneumoniae*, *H. influenzae* type b, *E. coli*, *Enterococcus faecalis*, *S. anginosus*, *Yersinia enterocolitica*, *Salmonella* spp., *Proteus mirabilis*, *Capnocytophaga sputigena*, and *Actinomyces* spp. also have been reported to cause hematogenously acquired abscesses.* Bacteremia secondary to intravenous drug abuse or the presence of central lines occasionally predisposes patients to developing this type of infection.[103,217] Rarely, tuberculous psoas abscesses have been reported, often as a complication of vertebral osteomyelitis.[199]

Pelvic muscle abscesses usually are drained by a percutaneous or surgical approach, and antibiotic therapy is based on Gram stain and culture results. Successful therapy with antibiotics alone has been reported.[133] Duration of treatment is individualized and depends on the child's response and the drainage techniques that were used.

LATE COMPLICATIONS

Most children who have undergone appendectomy or drainage of a pelvic abscess do not have late complications. Occasionally, patients develop signs of bowel obstruction from peritoneal adhesions. Some studies have suggested that the future risk for infertility is greater in women who have perforated appendices or pelvic abscesses, presumably because of adhesion formation that impairs the migration of ova in the reproductive tract.[138]

*References 21, 74, 85, 168, 224, 227.

*References 35, 41, 43, 46, 86, 94, 99, 104.

Although some retrospective studies have suggested that patients with appendectomies have a higher rate of developing malignancies later in life, prospective and controlled studies have failed to demonstrate this association.[44,136] Patients who have had appendicitis have been reported to be three times more likely to develop right inguinal hernias than individuals who have not had the appendix removed.[16] It is unclear whether there is a higher long-term risk for developing Crohn disease after appendicitis early in life, because recent studies have not confirmed earlier observations.[9,97]

CHAPTER 52

Pancreatitis

Thomas L. Kuhls

Pancreatitis was thought to be an uncommon cause of abdominal pain in children and a disease primarily of adults. Because of better recognition of symptoms in children and the more frequent use of medications that cause pancreatic inflammation, acute pancreatitis currently is being diagnosed more frequently in institutions specializing in pediatric care.[109,208]

Compared with causes of acute pancreatitis in adults—primarily alcoholism, cholelithiasis, and trauma—causes of childhood pancreatitis are more diverse. Microorganisms account for a significant proportion of cases of pancreatitis in children. In addition, antimicrobial agents have been associated with severe and occasionally fatal episodes of pancreatitis and bacterial infections may complicate the natural history of acute and chronic pancreatitis. Pediatricians who care for children with pancreatitis must have expertise in the diagnosis and treatment of infectious diseases.

CLINICAL MANIFESTATIONS

More than 80 percent of children with acute pancreatitis complain of abdominal pain.[121,208] Only 30 percent of pediatric patients have epigastric pain as usually described by adults, however.[205] In children, other sites of focal tenderness or diffuse pain include the right upper quadrant of the abdomen, the periumbilical area, the entire abdomen, and, less commonly, the right lower quadrant of the abdomen. The onset of pain usually is rapid and increases to a maximal intensity in a few hours, but occasionally the onset may be slow and gradual. Most often the pain is sharp and excruciating. Only one third of children complain of pain that radiates to other areas, including the back, lower part of the abdomen, upper abdominal quadrants, and anterior chest wall. In school-aged children the pain often intensifies after meals.

Two thirds of children with acute pancreatitis have vomiting.[21] Children younger than 5 years of age occasionally experience vomiting without abdominal tenderness.[215] Fever is present in only 30 percent of children with pancreatitis, but temperatures greater than 38.5 °C [101.3 °F] are observed occasionally.[205] Children may present with only the symptom of cough, and pleural effusions are found on radiography.[118]

On physical examination, children are classically found lying quietly on their sides with their knees flexed. They usually have epigastric tenderness to palpation and decreased or absent bowel sounds. Abdominal distention is found in 30 percent of children with pancreatitis and occurs more commonly in preschool-aged children.[205,215] Rebound tenderness, guarding of the epigastrium, jaundice, an abdominal mass, or ascites occasionally is detected. Rarely, ecchymoses of the flanks (Grey Turner

sign) or the umbilical area (Cullen sign) can be identified but usually only when life-threatening hemorrhagic pancreatitis is present. In severe pancreatitis, children may present with evidence of shock and multiple-organ failure.

Chronic pancreatitis occurs when irreversible damage in the pancreatic architecture causes abnormalities in the function of the pancreas.[110] Children with chronic pancreatitis often have lengthy or recurrent bouts of abdominal pain and vomiting.

LABORATORY DIAGNOSIS

The single most common useful laboratory test for the clinical diagnosis of pancreatitis in children is measurement of the serum amylase concentration, but the level correlates poorly with the severity of the disease. In most studies of childhood pancreatitis, the diagnosis is confirmed when the serum amylase level is greater than three times the normal level for the particular laboratory completing the test. The serum concentration rises quickly within hours after symptoms develop. High serum amylase concentrations can be observed, however, in numerous other illnesses, including acute cholecystitis, intestinal obstruction, perforations of abdominal organs, appendicitis, salpingitis, ruptured ectopic pregnancy, and salivary gland disease. The serum amylase concentration can return to normal in 24 to 72 hours after the onset of symptoms; therefore, the diagnosis of pancreatitis can be missed. In this situation, the urine amylase concentration can remain elevated for at least 1 week.

Serum amylase concentrations occasionally are not elevated during the course of pancreatitis in children.[155] In a series of children with pancreatitis, 83 percent of patients had elevated serum amylase levels.[208] In addition, marked hyperlipidemia may interfere with the laboratory measurement of amylase.[23] Serum lipase is useful in these situations; however, high serum concentrations often are not detected until 24 hours after the beginning of the illness. Because lipase is produced only in the pancreas and intestinal cells, measurement of its serum concentration helps distinguish children with high serum amylase concentrations of pancreatic as opposed to salivary origin. Some children with pancreatitis have high amylase levels without an elevation of serum lipase.[111]

Laboratory findings in children with severe acute pancreatitis may include leukocytosis with increased immature polymorphonuclear leukocytes, an elevated erythrocyte sedimentation rate, and elevated C-reactive protein level. In children with fulminate hemorrhagic pancreatitis, anemia develops quickly. Other associated findings include hyperglycemia, hypertriglyceridemia, hypoalbuminemia, and hypocalcemia. Although its validity has been questioned, a scoring system for children with pancreatitis has been devised in which severe pancreatitis is more likely when a child presents who is younger than 7 years of age, weighs less than 23 kg, has a total white blood cell count of more than 18,500 cells/mm^3, has an admission lactate dehydrogenase value greater than 2000, has a 48-hour calcium level less than 8.3 mg/dL, has a 48-hour albumin level less than 2.6 g/dL, has a 48-hour fluid sequestration less than 75 mL/kg/48 hr, and has a 48-hour rise in blood urea nitrogen greater than 5 mg/dL.[44,176] Procalcitonin levels may be useful in predicting severe pancreatitis and later complications in adults.[123] Elevated aminotransferase and alkaline phosphatase levels generally are observed only when the episode of pancreatitis is caused by biliary obstruction, such as in gallstone-related disease.

The radiographic features of childhood pancreatitis also are nonspecific. Radiographs of the abdomen may show localized ileus of the jejunum in the midepigastric or left upper quadrant region adjacent to the pancreas (sentinel loop), a distended transverse colon without visualization of the descending colon because of adjacent pancreatic inflammation (colon cutoff sign), duodenal distention with air–fluid levels, or loss of the left psoas shadow.[84] Occasionally, chest radiography reveals an elevated left hemidiaphragm or pleural effusion.

In recent years, the ability to diagnose pancreatitis in children has been improved greatly by ultrasonography.[208] The echodensity of the pancreas is normally equal to or greater than that of the left lobe of the liver. During acute pancreatitis, edema causes the gland to enlarge and become less dense than the liver. These two findings can aid in establishing the diagnosis of pancreatitis, and complications such as abscesses and pseudocysts can be identified. Also, ultrasonography may delineate dilations of the pancreatic ducts due to obstruction or ductal stones. Visualization of the pancreas by ultrasonography may be obscured because of overlying bowel gas. In such cases, computed tomography (CT) is useful in detecting pancreatic size and density.

CT of the pancreas should be performed in complicated cases of pancreatitis after a few days of treatment to determine the severity of disease and extent of pancreatic necrosis.[171] It is especially useful when surgery is being considered for drainage of abscesses and pseudocysts.

Endoscopic retrograde cholangiopancreatography (ERCP) is used in children with pancreatitis to treat gallstones, strictures, or *Ascaris* infection.[146,151] Because of ongoing improvement in image quality, magnetic resonance cholangiopancreatography (MRCP) is being increasingly used as a noninvasive technique for evaluating children with chronic or recurrent pancreatitis, with results similar to those from ERCP.[38,43,184]

NONINFECTIOUS CAUSES

A cause for childhood pancreatitis can be determined in more than 90 percent of cases if diagnostic evaluation is thorough, especially in children younger than 6 years of age.[109,215] The frequency of each specific cause depends on the patient population of the particular medical center. At Children's Hospital of Michigan, 33 percent of children with pancreatitis have biliary tract–related disease because of that institution's large patient population with sickle-cell anemia.[215] At Yale–New Haven Hospital, drug-related pancreatitis accounts for 30 percent of the total cases of childhood pancreatitis because of the frequent use of immunosuppressive and cancer chemotherapeutic

agents in that hospital.[84] The most common noninfectious causes of pancreatitis in children are listed in Table 52-1.

Trauma

In many older series of patients, trauma is the leading cause of acute pancreatitis in children. Because the highly vascular pancreas is immobilized by the stomach, duodenum, and vertebrae, it is susceptible to blunt and penetrating trauma. The less-developed abdominal wall musculature in pediatric patients may enhance their susceptibility to pancreatic injury after episodes of blunt trauma. Child abuse has been recognized increasingly as a cause of trauma-related pancreatitis.[140] Postoperative pancreatitis occurs most commonly after abdominal or cardiac surgery.[56] Pancreatitis also may be associated with traumatic brain injury in children.[195]

Medications

Medications used in pediatric practice increasingly are causing episodes of pancreatitis in children. In most pediatric studies, the anticonvulsant valproic acid is the most common medication associated with the development of pancreatitis, and its occurrence may be underreported.[67,208] The risk for developing pancreatitis does not depend on the serum level of valproic acid, and it is not related to the length of therapy.[169,207] Pancreatitis has also been observed in children taking the seizure medications zonisamide and lamotrigine.[152,165] Chemotherapeutic and immunosuppressive agents such as azathioprine, steroids, 6-mercaptopurine, methotrexate, L-asparaginase, and ifosfamide have been associated with cases of childhood pancreatitis, and other immunosuppressive agents most likely play a role in post transplant pancreatitis.* Acute pancreatitis has been associated rarely with the use of diuretics, including hydrochlorothiazide and furosemide[115]; growth hormone[26]; sulfasalazine[65]; atypical antipsychotics[77,104]; statins[96]; propofol[31]; nonsteroidal inflammatory agents, including ibuprofen[112,113]; metformin[59]; proton pump inhibitors[212]; angiotensin-converting enzyme inhibitors and angiotensin receptor antagonists[14]; estrogens; and codeine. Alcohol consumption is an uncommon cause of pancreatitis in younger children; however, it can cause illness occasionally in the adolescent population.

Physicians with expertise in the management of infectious diseases are becoming more aware of drug-induced pancreatitis because many antimicrobial agents can cause pancreatic inflammation. Pentamidine isethionate has been used in the treatment of *Pneumocystis jejuni* pneumonia, African trypanosomiasis, and leishmaniasis. It may cause hypoglycemia because of toxicity to pancreatic islet cells and is associated with severe and occasionally fatal episodes of pancreatitis.[122,216] In children and adults, aerosolized pentamidine prophylaxis for *P. jejuni* pneumonia also has been associated with severe cases of pancreatitis in patients with acquired immunodeficiency syndrome (AIDS).[80,122] Similarly, pentavalent antimonial

TABLE 52-1 **Noninfectious Causes of Childhood Pancreatitis**

Trauma
Blunt
Brain injury
Penetrating
Postoperative

Drugs
Angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor antagonists
Antiepileptic agents (valproic acid, zonisamide, lamotrigine)
Antimicrobial agents (pentamidine, antimonials, sulfonamides, tetracycline, macrolides, metronidazole, dapsone, nitrofurantoin, tigecycline, isoniazid, ceftriaxone, gatifloxacin, nucleoside analogue reverse transcriptase inhibitors, interferon-α, liposomal amphotericin B, micafungin, itraconazole)
Atypical antipsychotic agents
Chemotherapeutic/immunosuppressive agents (azathioprine, corticosteroids, asparaginase, 6-mercaptopurine, tacrolimus, methotrexate, ifosfamide)
Diuretics (thiazides, furosemide)
Estrogens
Ethyl alcohol
Growth hormone
Metformin
Pain medications (nonsteroidal inflammatory agents, codeine)
Propofol
Proton pump inhibitors
Statins
Sulfasalazine

Obstructive Diseases
Anatomic abnormalities
Cholelithiasis

Genetic and Metabolic Diseases
Aminoacidurias
Cystic fibrosis
Diabetes mellitus
Glycogen storage disease type 1
Hyperlipoproteinemia types I, IV, and V
Hyperparathyroidism
Hypertriglyceridemia
Recurrent hereditary pancreatitis

Vasculitic and Autoimmune Diseases
Crohn disease
Henoch-Schönlein purpura
IgG4 autoimmune pancreatitis
Kawasaki syndrome
Systemic lupus erythematosus

Miscellaneous
Anticholinesterase insecticide intoxication
Chronic fibrosing pancreatitis
Lymphoma
Reye syndrome
Scorpion stings
Tropical chronic pancreatitis
Orthotopic liver transplantation

agents such as sodium stibogluconate and meglumine antimonite, used for the treatment of visceral leishmaniasis, can induce pancreatic inflammation.[12,161]

Sulfonamides, including trimethoprim-sulfamethoxazole, have been implicated occasionally as a cause of acute pancreatitis in adults.[8,199] Symptoms have recurred when patients have been reexposed to the medication. The abdominal pain often is accompanied by a hypersensitivity-type rash. Tetracycline-induced pancreatitis has been described in children with and without overt liver disease.[55,187] In addition, clarithromycin,[69,159] erythromycin,[179] rifampin,[145] roxithromycin,[149] dapsone,[42] nitrofurantoin,[130] isoniazid,[94] tigecycline,[148] and metronidazole[136] have been added to the list of agents that can cause pancreatitis in previously healthy individuals when given in routine doses or when high amounts are consumed. Although uncommonly used in children, quinolone antibiotics, such as gatifloxacin, have been associated with hepatotoxicity and acute pancreatitis.[40] An adolescent who was receiving ceftriaxone also has developed pancreatitis secondary to obstruction of the biliary tract from gallstones.[117]

Pancreatitis has been a major dose-limiting toxic effect of the human immunodeficiency virus (HIV)-inhibiting nucleoside analogue reverse transcriptase inhibitor (NRTI) class of medications because of mitochondrial toxicity, especially dideoxyinosine, in adult and pediatric patients.[32,61] Most episodes of pancreatitis occur when the dose is 360 mg/m^2/day or more, and usually the pancreatic inflammation resolves when the medication is discontinued. Concomitant administration of pentamidine or another NRTI, such as ribavirin, used in the treatment of hepatitis C infection with dideoxyinosine, may increase the risk for developing pancreatitis.[125] In pediatric patients with AIDS, serum amylase concentrations often are elevated in patients without pancreatic symptoms, whereas children with pancreatitis can have normal serum amylase concentrations. The serum lipase concentration is useful in evaluating HIV-infected children for possible pancreatic inflammation.[32,122] Increased liver aminotransferase or lipase concentrations before the administration of dideoxyinosine may be helpful in predicting the children in whom pancreatitis would develop.[32] In all children with symptoms consistent with pancreatitis, dideoxyinosine should be withheld pending the results of a lipase assay, and it should be discontinued if the concentration is elevated. Similarly, dideoxyinosine should be discontinued for 1 week after treatment with pentamidine for *P. jejuni* pneumonia.[60] Because of increased awareness of NRTI toxicity, the incidence rate of pancreatitis in HIV-infected children in the highly active antiretroviral therapy (HAART) era appears to be decreasing.[126]

Interferon-α, which is used in the treatment of chronic hepatitis and malignancies, also has been associated with the development of pancreatitis.[37] The antifungal agents liposomal amphotericin B, micafungin, and itraconazole rarely cause pancreatic toxicity.[144,156,175]

Obstructive Diseases

Obstruction of the common bile duct, pancreatic duct, or sphincter of Oddi may cause pancreatitis. Gallstones or congenital anatomic malformations, including an annular pancreas, pancreas divisum, choledochal cysts, and enteric duplication cysts, can cause pancreatitis by obstructing normal pancreatic flow.[7,70,87,89] Pancreatitis observed in children with sickle-cell anemia may be caused by obstruction from stones, biliary sludge, pancreatic microvascular occlusion, and ischemia during crises.[4]

Genetic and Metabolic Diseases

Metabolic diseases often are associated with chronic recurrent episodes of pancreatitis. Such diseases include hyperlipoproteinemias, hypertriglyceridemias, cystic fibrosis, diabetes mellitus, hyperparathyroidism, aminoacidurias, and glycogen storage disease type I.* Recurrent hereditary pancreatitis usually occurs in an autosomal dominant pattern, with onset taking place between infancy and adolescence. Mutations in the genes encoding cationic trypsinogen *(PRSS1)*, the serine protease inhibitor Kazak type 1 *(SPINK1)*, and chymotrypsinogen C *(CTRC)* have been associated with hereditary pancreatitis.[153] Other children and adults with chronic pancreatitis have been shown to have mutations in the cystic fibrosis transmembrane regulator *(CFTR)* gene similar to individuals with cystic fibrosis.[46,192]

Vasculitic and Autoimmune Diseases

Pancreatitis also can occur in syndromes in which vasculitis is a major component of the disease process. It has been associated with common pediatric disorders, including Kawasaki syndrome, Henoch-Schönlein purpura, Crohn disease, and systemic lupus erythematosus.[106,134,174,201]

Rarely, children develop pancreatitis from an autoimmune process. Children usually present with a mass in their pancreas and are diagnosed when IgG4 levels are elevated in the serum and there is histologic infiltration of IgG4-bearing plasma cells surrounding the medium and large interlobular ducts of the pancreas.[24,214]

Miscellaneous Causes

Although no longer common, Reye syndrome has been associated with acute pancreatitis.[68] The venom of the scorpions *Tityus trinitatus*, *Tityus asthenes*, and *Leiurus quinquestriatus* can cause pancreatitis in patients who have been stung; however, these species do not live naturally in the United States.[19,141,170] The gastrointestinal symptoms observed in children with anticholinesterase insecticide poisoning may be caused by pancreatitis.[206] Also, tropical chronic pancreatitis seen in developing countries is most likely related to malnutrition and dietary intake of toxins, such as those from the tuber cassava.[18] Rarely, primary pancreatic lymphoma may manifest in children as acute pancreatitis.[54] Chronic fibrosing pancreatitis in which the pathogenesis of the disease process remains unsolved only occurs rarely in the United States.[78]

Although a much less common occurrence than in adults, acute pancreatitis after orthotopic liver transplantation is severe in children and often results in death.[185,186]

*References 22, 30, 74, 75, 119, 197.

The cause of pancreatitis in liver transplant recipients most likely is multifactorial but probably involves traumatic injury, biliary obstruction, and immunosuppressive therapy.

INFECTIOUS CAUSES

Infections caused by various microorganisms have been shown by culture, histologic examination, or antibody titer rise during the course of acute pancreatitis in humans (Table 52-2). A true causal relationship usually is not shown. Although not all of the following infectious agents have been shown to be associated with childhood pancreatitis, they must be considered as possible etiologic agents because adult patients with infectious pancreatitis have been described. Compared with previous decades, infectious agents are being encountered less as a cause of acute pancreatitis, most likely because of mumps vaccination.

TABLE 52-2 **Microorganisms Associated with Episodes of Acute Pancreatitis**

Viruses
Adenoviruses
Cytomegalovirus
Epstein-Barr virus
Group B coxsackieviruses
Hepatitis A virus
Hepatitis B virus
Hepatitis E virus
Herpes simplex viruses
Human immunodeficiency virus
H1N1 influenza A virus
Measles virus
Mumps virus
Parainfluenza viruses
Rotavirus
Rubella virus
Varicella-zoster virus
West Nile virus

Parasites
Ascaris lumbricoides
Clonorchis sinensis
Cryptosporidium parvum
Echinococcus granulosus
Fasciola hepatica
Plasmodium falciparum
Taenia saginata
Toxoplasma gondii
Wuchereria bancrofti

Mycoplasmas and Bacteria
Brucella melitensis
Campylobacter jejuni
Escherichia coli
Legionella spp.
Leptospira spp.
Moraxella catarrhalis
Mycobacterium tuberculosis
Mycoplasma pneumoniae
Salmonella spp.
Streptococcus pyogenes
Yersinia spp.

Fungi
Aspergillus spp.
Candida spp.
Cryptococcus neoformans

Viral Infections

Group B coxsackieviruses and mumps virus are the best documented causes of pancreatitis in children. Group B coxsackieviruses usually cause pancreatitis along with other clinical manifestations, including aseptic meningitis, mild diarrhea, rash, and myocarditis.[34,90] They rarely have caused death in young infants with myocarditis and pancreatitis.[47] How commonly these enteroviruses cause pancreatic inflammation is unknown. Thirty-one percent of patients with aseptic meningitis during an epidemic of group B coxsackievirus infection had increased serum amylase concentrations.[129] Numerous studies have shown coxsackievirus B–induced damage to pancreatic acinar cells in mouse models of infection, and it is believed that the pancreas is the primary replication site for these viruses.[86,189] Coxsackievirus B strains have caused worsening bouts of pancreatic disease in children with chronic pancreatitis and the primary episode of pancreatitis in children later found to have the hereditary form of disease.[71,167]

Usually, mumps pancreatitis occurs in the presence of parotitis; however, abdominal pain and vomiting may occur for days before the development of salivary swelling.[203] Rarely, mumps virus can cause pancreatitis without other common clinical manifestations.[127,196] Because more than 80 percent of children with mumps parotitis have elevated serum amylase concentrations, ultrasonography and serum lipase concentrations should be obtained to aid in establishing the diagnosis.[76] An estimated 15 percent of children with mumps virus infection have abdominal tenderness and vomiting suggestive of the diagnosis of pancreatitis.[84] In only a single report has the pancreatitis been hemorrhagic and severe.[57] Occasionally, chronic or recurring pancreatitis develops after mumps infection.[211]

Researchers previously thought that acute pancreatitis occurred in cases of viral hepatitis only when fulminate liver disease developed. Increasingly, children with mild hepatitis A infection and pancreatitis are being described.[3] In addition, a 16-year-old with acute hepatitis A infection died of severe pancreatitis with multiple-organ failure.[100] Individuals with acute hepatitis and pancreatitis have also been found to have hepatitis E viral infection.[181] Hepatitis B viral antigens have been detected in the pancreatic glandular cells of patients with severe acute hemorrhagic pancreatitis.[164] The role of hepatitis B virus in the pathogenesis of pancreatic inflammation in these patients is unknown; however, a young adult has developed three episodes of acute pancreatitis during acute exacerbations of chronic hepatitis B infection that resolved after lamivudine therapy.[39] It has been suggested that edema of the ampulla of Vater caused by biliary

sludge formed during hepatitis viral infection leads to outflow obstruction of pancreatic fluid and the development of pancreatitis.[92]

Human herpesviruses are uncommon causes of childhood pancreatitis in immunocompetent patients. Occasionally, pancreatitis develops in children and adolescents with infectious mononucleosis.[101] Acute pancreatitis and, occasionally, pseudocyst formation also have been reported in previously healthy individuals with varicella infection.[62,188] In addition, previously healthy adults have developed pancreatitis during primary cytomegalovirus and herpes simplex virus infections.[99,105,139]

Interstitial pancreatitis occurs relatively commonly in children with congenital rubella syndrome.[124] In addition, severe pancreatitis has been identified in immunocompetent patients with mild and fatal measles virus infection.[64,198] An adolescent has been described with measles encephalitis and pancreatitis that responded to corticosteroids.[177] Rarely, other viruses including adenovirus, West Nile virus, rotavirus, and H1N1 influenza A virus have been associated with the development of pancreatitis in previously healthy adults and children.[25,28,102,143]

Viral pancreatitis also occurs in immunocompromised patients. Cytomegalovirus has been identified in pancreatic specimens obtained during autopsies of patients who had AIDS, transplant recipients, individuals taking corticosteroids for autoimmune diseases, and cancer chemotherapy patients.[91,95,180] The symptoms of pancreatitis have resolved in a few patients with AIDS treated with ganciclovir or foscarnet.[41] Adenovirus has caused hemorrhagic pancreatitis and death in children with bone marrow transplants, whereas an infant with disseminated adenoviral infection and pancreatitis survived with cidofovir therapy.[20,36,135] Researchers have suggested that stool cultures for adenoviruses should be obtained when post-transplant patients develop pancreatitis. Varicella-zoster and herpes simplex viruses have also caused pancreatitis and death in patients with various immunodeficient conditions.[58,166] A disseminated parainfluenza virus infection in an infant with severe combined immunodeficiency was associated temporally with the development of pancreatitis; however, no attempt was made to culture the virus from postmortem pancreatic tissue.[63]

Whether HIV directly causes pancreatitis is unclear. Laboratory-diagnosed episodes of pancreatitis in adults and children with AIDS do occur, but whether the pancreatic inflammation is caused by HIV or an unrecognized opportunistic pathogen is unknown.[213] HIV-infected children frequently have elevated amylase and lipase levels with no correlation to antiviral therapy.[35] Increasing numbers of adults with primary manifestations of HIV infection have presented with acute pancreatitis, suggesting a role of HIV in the pathogenesis of the disease.[193]

Parasite Infestations and Infections

Ascaris lumbricoides can migrate in the intestines to the ampulla of Vater and subsequently to the pancreatic duct or common bile duct. Obstruction of the biliary or pancreatic duct can cause acute pancreatitis.[2,13,15,178] Ascariasis is diagnosed when adult roundworms are identified in the duodenum by radiographs of the upper gastrointestinal tract (Fig. 52-1) or more commonly by ultrasonography or ERCP. Often, a history of seeing worms in the feces can be elicited. The flukes *Clonorchis sinensis* and *Fasciola hepatica* and the cestode *Taenia saginata* also can migrate to the pancreatic and biliary drainage systems and cause pancreatitis.[53,108,168] Rarely, hepatic hydatid cysts caused by *Echinococcus* can obstruct biliary drainage and cause pancreatic inflammation.[97] *Wuchereria bancrofti* occasionally has been found to cause chronic pancreatitis.[93] Parasitic infestations should be considered as a cause of pancreatitis, particularly in immigrant children and patients who have traveled to developing nations.

FIGURE 52-1 ■ An ascaris close to the ampulla of Vater, with the body and tail lying in the second and third parts of the duodenum. The patient is a 9-year-old girl with acute pancreatitis.

The protozoan *Cryptosporidium parvum* has been identified in the bile of an AIDS patient with elevated serum amylase levels and right upper quadrant abdominal pain.[72] ERCP demonstrated biliary and pancreatic ductal disease, but no other opportunistic pathogens were isolated. Cryptosporidia also have been observed in the interlobular pancreatic ducts of experimentally infected immunocompromised mice.[194] Whether cryptosporidial infection causes pancreatitis in immunocompetent patients is unknown; however, a previously healthy adolescent developed pancreatitis after having cryptosporidial diarrhea.[81] *Toxoplasma gondii* cysts have been found in the postmortem pancreatic tissue of patients with AIDS.[5,85]

Rarely, pancreatitis occurs during acute episodes of *Plasmodium falciparum* malaria.[182] Other systemic manifestations of malaria that often are present include high fever, hepatitis, intestinal malabsorption, encephalitis, and pulmonary insufficiency.

Mycoplasmal and Bacterial Infections

In older children and adults, moderately severe symptoms of pancreatitis have occurred just before or during the course of atypical pneumonia.[6,83] Most patients have had cold agglutinins in their sera, and all have had significant changes in *Mycoplasma pneumoniae* antibody titer. Some controversy has ensued over whether *M. pneumoniae* can cause acute pancreatitis without evidence of pneumonia. Although complement-fixing IgM antibodies against *M. pneumoniae* often increase significantly during the course of acute pancreatitis, researchers have argued that pancreatic cellular antigenic components similar to *Mycoplasma* lipid antigens are exposed during the disease process and that the antibodies elicited cross react in *Mycoplasma* serologic assays.[107] Rarely, *Mycoplasma* has caused severe necrotizing pancreatitis.[128]

Along with *M. pneumoniae* infection, legionnaires' disease must be considered when acute pancreatitis develops along with pneumonia.[121,209] Miliary tuberculosis also can cause symptoms of pancreatitis.[154] Pancreatitis may occasionally be the only manifestation of tuberculosis and is usually diagnosed by fine-needle aspiration of the pancreas.[79,131]

Common pyogenic bacteria usually do not cause acute pancreatitis. Secondary invasion of inflamed pancreatic tissue does occur. Some evidence exists that circulating endotoxin from *Escherichia coli* can cause extrahepatic cholestasis and pancreatitis.[48] Acute pancreatitis also has been seen in children with hemolytic-uremic syndrome.[150,157] Pancreatitis can occur during acute episodes of enteritis. *Salmonella typhimurium*, *Salmonella typhosa*, *Campylobacter jejuni*, *Yersinia enterocolitica*, and *Yersinia pseudotuberculosis* all have been reported to cause clinically evident and laboratory-confirmed cases of pancreatitis.[11,45,120,160] There have been single reports of *Moraxella catarrhalis* and *Streptococcus pyogenes* causing severe pancreatitis in young children.[1,138]

Pancreatitis has been reported in children with leptospirosis.[137,172] *Brucella melitensis* also has been added to the list of uncommon causes of acute pancreatitis.[142] *Helicobacter pylori* has been suggested to influence the clinical course of pancreatitis in humans, but data are still lacking to imply a role in pancreatic pathology.[116]

Fungal Infections

Fungal infections have not been reported to cause acute pancreatitis in immunocompetent patients. *Aspergillus* has caused fatal hemorrhagic pancreatitis, however, in an adult patient with cancer who was undergoing chemotherapy.[73] *Candida* spp. and *Cryptococcus neoformans* have been isolated from the pancreatic tissue of patients with AIDS, but whether they cause clinical symptoms of pancreatitis is unknown.[213]

PATHOGENESIS

Enzymes for polysaccharides, fats, and proteins are produced and stored in pancreatic acinar cells. They exist intracellularly in an inactive precursor form. After cholecystokinin-pancreozymin stimulation, the proenzymes are released into the pancreatic ducts and flow into the duodenum. The enzymes normally do not become enzymatically active until they reach the intestinal lumen.

When trypsinogen is activated prematurely to trypsin within the pancreatic acinar cells, autodigestion occurs within the pancreas. The mechanisms that activate trypsinogen and other proteolytic enzymes during specific pathologic processes have not been well elucidated. Drug-induced and infectious causes of pancreatitis are thought to be due to direct toxic effects on acinar cells. Gallstones, *Ascaris* infection, and congenital abnormalities are thought to damage acinar cells by obstructing pancreatic flow. Traumatic pancreatitis probably occurs as a result of direct injury to the glandular cells, whereas vasculitis may cause changes in pancreatic blood flow, causing ischemia.

Autodigestion of the pancreas causes edema of pancreatic tissue, and microcirculation may be compromised, leading to ischemia, hemorrhage, or necrosis. An inflammatory response develops, which may be mild, as occurs in episodes of infectious pancreatitis, or may be more severe with hemorrhagic necrosis. Major mediators of the intense immune response include chemoattractant chemokines and their upregulated receptors; cytokines including tumor necrosis factor, interleukin (IL)-1, IL-6, and IL-8; and platelet-activating factor.[114,162] If an imbalance of the proinflammatory response occurs within the pancreas, a systemic inflammatory response including shock may occur, leading to high morbidity and mortality. Also, sepsis may occur because of extensive necrotic tissue within the pancreas and translocation of microorganisms from the intestines.

TREATMENT

Despite increasing recognition of cases of childhood pancreatitis, no major pharmacologic advances have been made in the treatment of the disease since the mid 1970s. Animal data have shown that medications such as glucagon, aprotinin, gabexate mesilate, 5-fluorouracil, octreotide, somatostatin, probiotics, and vitamin-based antioxidants may be useful in the treatment of pancreatitis; however, trials in adults have not substantiated their efficacy.[16,49,163] The continuing main objectives of treatment are to relieve abdominal pain and treat aggressively systemic manifestations, such as shock, electrolyte abnormalities, and anemia. Meperidine continues to be the medication most commonly used for controlling pain.

In the past, children were kept in the fasted state and nasogastric suction was applied to decrease duodenal acid–stimulated secretin release. Feeding with carbohydrate solutions was not restarted until all symptoms had

resolved. Meta-analyses in adults, however, have shown that feeding with a low-fat elemental diet decreases the complication rate of patients with acute pancreatitis and now is considered the treatment of choice over total parenteral nutrition.[9,33] Intravenous fluids and colloids are used during the acute episode to maintain intravascular volume. During the entire course of acute pancreatitis, the hematologic and biochemical parameters of the child must be monitored closely.

If the episode of pancreatitis is drug induced, use of the medication should be curtailed immediately. Often, the symptoms recur if the medication is restarted. Pancreatitis caused by *M. pneumoniae* or bacteria should be treated with proper antimicrobial agents. Obstructions to pancreatic flow (e.g., gallstones, roundworms, congenital abnormalities) may have to be excised or altered either by surgery or endoscopy.[27,98,146]

COMPLICATIONS

During the acute episode of pancreatitis, the systemic inflammatory response syndrome may develop, leading to renal, hematologic, central nervous system, pulmonary, and cardiovascular complications. In 12 percent of children with pancreatitis, an inflammatory mass develops in the first weeks after the onset of illness; however, these masses more commonly occur after trauma.[202] Continued or increasing abdominal pain, nausea, or vomiting often accompanies the development of a phlegmon, abscess, or pseudocyst. An inflammatory phlegmon usually develops into a thin-walled pseudocyst of the lesser sac but may become secondarily infected and induce the formation of an abscess. Patients in whom an inflammatory mass develops must be monitored closely with frequent physical examinations and serial CT studies. In children with pseudocysts, acute abdominal pain accompanied by hypotension often signifies bleeding into the pseudocyst or rupture of the pseudocyst into the peritoneum. Slowly leaking pseudocysts may cause pancreatic ascites. Pseudocysts should be treated conservatively but have to be resected surgically, drained externally, or drained by endoscopy when complications occur.[10,173] Approximately 33 percent of pseudocysts resolve spontaneously within 6 weeks.[147]

The development of fever and leukocytosis during the course of pancreatitis should suggest an infected pseudocyst, pancreatic abscess, or sepsis. In adults, infectious complications account for 80 percent of deaths associated with acute pancreatitis.[29] Isolates from pancreatic abscesses and necrotic pancreatic tissue have yielded intestinal flora, including anaerobes, in more than 90 percent of cases, but *Candida* spp. are being isolated more frequently in many medical centers.[50,191] Rarely, *Streptococcus pneumoniae* can be isolated from infected pancreatic tissues of adults with chronic pancreatitis.[183] Carbapenems, such as imipenem and meropenem, are used commonly to treat adult patients with suppurative complications of pancreatitis because these antibiotics penetrate well into pancreatic tissues and have activity against intestinal flora.

Even with early diagnosis, proper antibiotics, and surgical intervention using interventional drainage procedures, necrosectomy, or open surgery, the death rate from pancreatic abscesses reaches 27 to 57 percent in adults.[88] Performing percutaneous catheter drainage under CT guidance may reduce the mortality rate associated with treating pancreatic abscesses.[17] Rarely, fistulas from pseudocysts or abscesses to other abdominal organs may develop.[82]

The role of prophylactic antibiotics in preventing the suppurative complications of acute pancreatitis remains controversial despite 3 decades of debate. Most recent meta-analyses on the subject conclude that prophylactic antibiotics do not prevent pancreatic necrosis from being infected and do not prevent death, although a poorly powered 2010 Cochrane review suggests that imipenem may reduce the number of pancreatic infections.[133,200,210] Infections, when they do occur after the administration of prophylactic antimicrobial agents, often are caused by multiresistant bacteria or by fungi.

Osteolytic lesions resembling osteomyelitis may develop weeks to months after an acute episode of pancreatitis.[132] Elevated systemic levels of lipase activity possibly may cause intramedullary fat necrosis in the bone. Usually, the lesions are asymptomatic and resolve spontaneously without therapy.

CHAPTER 53

Peritonitis and Intra-Abdominal Abscess

Judith R. Campbell

Intra-abdominal infection can be a life-threatening condition that occurs spontaneously or as a result of intra-abdominal disease, injury, or surgery. Given the compartmental anatomy and physiology of the abdominal cavity, intra-abdominal infection frequently is categorized as peritonitis, intraperitoneal abscess, retroperitoneal abscess, and visceral abscess.[3] In this chapter peritonitis and intra-abdominal abscess are reviewed; liver abscess, appendicitis and pelvic abscess, and retroperitoneal abscess, are reviewed in Chapters 49, 51, and 54, respectively.

PERITONITIS

ANATOMY

Knowledge of the anatomic relationships within the abdomen is important for understanding the source and routes of spread of infection. The peritoneal cavity extends from the undersurface of the diaphragm to the pelvis. In males it is a closed space, whereas in females the ends of the fallopian tubes penetrate into the peritoneal cavity. The transverse mesocolon and greater omentum separate the upper and lower peritoneal cavity. Peritoneal reflections divide the intraperitoneal space further into several compartments: the lesser sac, the paracolic gutters, and the subhepatic and subphrenic spaces (Fig. 53-1). The most dependent area of the peritoneal cavity is the pelvis. Exudate can extend to any of the recesses within the peritoneal cavity distant from the original source, however, and cause diffuse inflammation.[3] When inflamed, the anterior parietal peritoneum, which is supplied by somatic afferent nerves, gives the sensation of localized pain. Stimulation of the visceral peritoneum causes dull, poorly localized pain.

PATHOGENESIS

Peritonitis is defined as inflammation of the serosal lining of the abdominal cavity or the peritoneum and may be caused by any chemical or infectious agent that irritates the peritoneal surfaces. Noninfectious peritonitis is caused by extravasation of irritants, such as gastric juice, bile, urine, blood, pancreatic secretions, or the contents of a ruptured cyst, into the peritoneal cavity. Although chemical peritonitis generally is aseptic, it may be an important antecedent event to the development of infectious peritonitis.

After peritoneal contamination by bacteria has occurred, the first mechanism of host defense is lymphatic clearance. In experimental peritonitis, this clearance is so efficient that peritonitis and abscess formation occur only if adjuvant substances, such as hemoglobin or necrotic tissue, are present.[24,25,48] In the first hours after bacterial contamination occurs, local resident macrophages are the predominant phagocytic cells. The macrophages then are cleared by the lymphatic system. After bacterial proliferation occurs, polymorphonuclear leukocytes become more numerous in the peritoneal cavity, and inflammation ensues. These peritoneal defense mechanisms also have adverse effects. Fibrin is deposited, which potentially entraps bacteria into a sequestered environment. An increase in splanchnic blood flow causes exudation of fluid into the peritoneal space, further impairing host defenses by diluting important peritoneal opsonins.[24,25] These host responses serve as a means of containing infection, but they also may contribute to the formation of abscesses.

Infectious peritonitis is subdivided into primary and secondary peritonitis based on the pathophysiology of the infection. Peritonitis that is associated with peritoneal dialysis or the presence of a ventriculoperitoneal shunt is a unique form of peritonitis that also is reviewed in this chapter. The microbial causes of peritonitis vary with the underlying cause and are summarized in Table 53-1.

PRIMARY PERITONITIS

Primary, or spontaneous, bacterial peritonitis is a rare infection defined as bacterial peritonitis in the absence of intra-abdominal findings, such as intestinal perforation. The incidence of spontaneous peritonitis in children is unknown; however, in the early 20th century, 8 to 10 percent of abdominal emergencies requiring surgical intervention were due to spontaneous peritonitis.[17,73] Freij and colleagues[30] conducted a 22-year review of

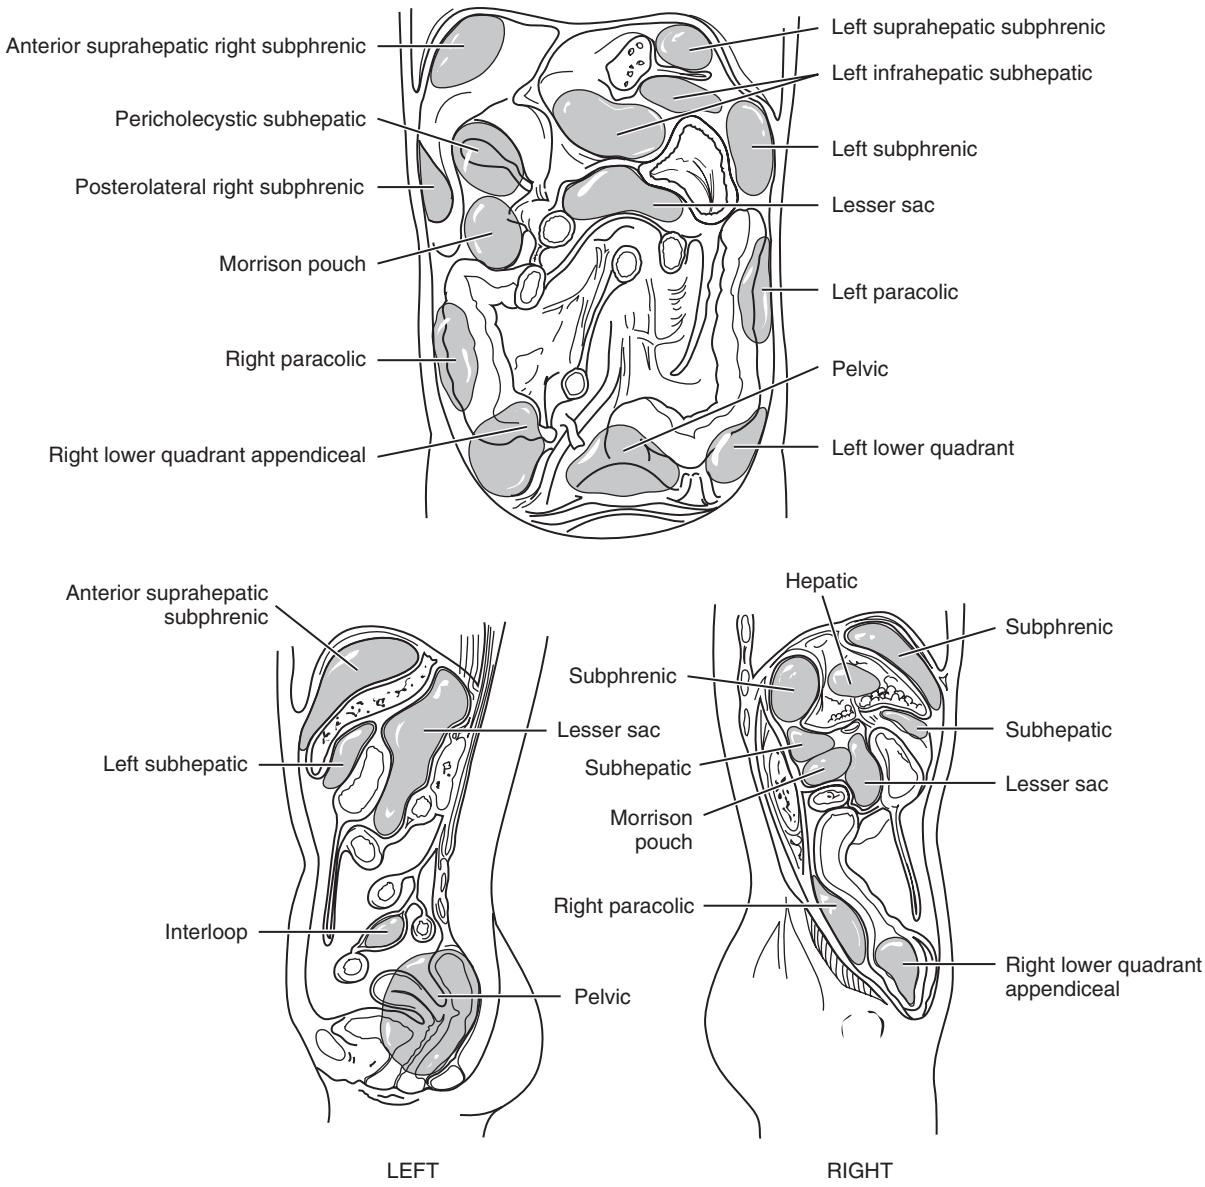

FIGURE 53-1 ■ Anterior and sagittal views of the peritoneal cavity. (From Altemeier WA, Culbertson WR, Fullen WD. Intra-abdominal sepsis. *Adv Surg* 1971;**5**:281–3.)

children with primary peritonitis in Dallas, Texas. Primary peritonitis was diagnosed in seven previously healthy children compared with 1840 cases of appendicitis during the same period. Currently, 1 to 2 percent of abdominal emergencies requiring surgical intervention are due to primary peritonitis.[39,42]

Now that this condition frequently is recognized clinically with the assistance of computed tomography (CT), the diagnosis often is made without exploratory laparotomy. The peak incidence of spontaneous peritonitis in children occurs when they are 5 to 9 years of age. In children, the most common predisposing factor is nephrotic syndrome, but this form of peritonitis also occurs in children with postnecrotic cirrhosis.* Spontaneous peritonitis rarely develops in previously healthy individuals without underlying conditions.[34,49]

The exact pathophysiologic mechanism for primary peritonitis is unknown; however, hematogenous inoculation is thought to be the most likely mechanism because the same organism frequently is recovered from cultures of blood and peritoneal fluid.[17,33,39] Alternative mechanisms include peritoneal seeding via the lymphatics, transmural migration through edematous bowel, and ascending infection from the female genitourinary tract.[33,39] In certain cases, impaired host defenses allow proliferation of bacteria that invade the peritoneal cavity, but a few children with primary peritonitis have no apparent impaired defense. Ascitic fluid from patients with nephrotic syndrome or cirrhosis contains lower levels of complement and immunoglobulin than does peritoneal fluid from a healthy host.[17,73,81] Deficiency of these important opsonins diminishes the natural clearance of organisms from the peritoneal cavity. Proliferation of organisms triggers the influx of phagocytes,

Other fungi	*Pseudomonas*
Pseudomonas	*S. aureus*
S. aureus	
Stenotrophomonas	

CAPD, continuous ambulatory peritoneal dialysis; *VP,* ventriculoperitoneal.

release of inflammatory mediators, and localized or diffuse peritoneal irritation that gives rise to symptoms of abdominal pain and fever.

Since the preantibiotic era, researchers have recognized that primary peritonitis frequently is caused by *Streptococcus pneumoniae*,[33] *Streptococcus pyogenes*,[34] and *Staphylococcus aureus.*[17] Rarely, primary peritonitis in prepubescent girls is caused by extension of upper genital tract *S. pneumoniae* infection.[39,68] Since the 1960s, the bacteriology of primary peritonitis has shifted to include an increased proportion of infections caused by gram-negative enteric organisms, such as *Escherichia coli* and *Klebsiella* spp.[17,39,43,74,81] In some instances, primary *E. coli* peritonitis may occur concurrently with bacteremic urinary tract infection.

Tuberculous peritonitis may be caused by *Mycobacterium tuberculosis* or *Mycobacterium bovis.* It may occur as a complication of primary mycobacteremia or be caused by reactivation of latent intra-abdominal infection within lymphoid tissue, but only rarely does it seem to occur as a function of the ingestion of swallowed organisms from a pulmonary primary focus.[36,37,67,78] Peritoneal infection with *M. bovis*, which is clinically similar to *M. tuberculosis* peritonitis, is acquired from unpasteurized dairy products and has been reported in children living along the border between the United States and Mexico. These organisms may cause peritonitis from either mycobacteremia or erosion of organisms through the mesenteric lymph nodes or bowel wall into the peritoneal cavity.[20] *Salmonella* spp. rarely cause primary peritonitis and have been reported primarily in patients with underlying conditions.[49]

SECONDARY PERITONITIS

Secondary peritonitis, the most common form of peritonitis, arises as a complication of intra-abdominal injury or disease when microorganisms, secretions, and the particulate material of an intra-abdominal organ enter the peritoneal cavity. Congenital or acquired conditions that result in ischemia, inflammation, or perforation of abdominal viscera may be complicated by secondary peritonitis.[23,48,70] In premature infants, necrotizing enterocolitis is the most common cause of secondary peritonitis.[53] In infants and children, appendicitis is the most common cause; however, it also may occur with volvulus, intussusception, incarcerated hernia, or rupture of a Meckel diverticulum.[53] Although less common in children than in adults, peritonitis also occurs as a complication of mucosal diseases, such as peptic ulcer, ulcerative colitis, Crohn disease, and pseudomembranous colitis.[53]

Rupture of or injury to an intra-abdominal viscus results in spillage of the luminal contents and contamination of the peritoneal cavity with bacteria, gastrointestinal secretions, and debris. Chemical and infectious sources of inflammation are introduced. The stomach and upper gastrointestinal tract contents contain only 10^3 to 10^4 or fewer organisms per gram because of the low pH of gastric secretions. Gram-negative aerobic organisms colonize the upper gastrointestinal tract. In contrast, the colonic contents have predominantly anaerobes, with 10^{11} anaerobes and 10^8 aerobes per gram.[11,23,39,66,70]

Secondary peritonitis usually is a polymicrobial infection, with 5 to 10 different bacterial species of anaerobes and facultative gram-negative bacilli. Synergy among the various bacterial species enhances bacterial proliferation.[11,70] Members of the *Bacteroides fragilis* group and *Peptostreptococcus* spp. are the anaerobic organisms reported most commonly in secondary peritonitis. Of the aerobic organisms, *E. coli*, *Klebsiella* spp., *Pseudomonas aeruginosa*, and *Enterococcus* spp. are isolated most often. More recently, *P. aeruginosa* has been noted to be present in 20 to 30 percent of children with complicated ruptured appendicitis.[8,23,40,70] When secondary peritonitis occurs in patients with a history of prolonged hospitalization, underlying chronic conditions, or recent antibiotic therapy, the etiology may include nosocomial pathogens that have colonized the gastrointestinal tract, such as *P. aeruginosa*, *Enterobacter* spp., *Acinetobacter* spp., or other antibiotic-resistant organisms.

Focal suppurative infection may be present within an intra-abdominal or retroperitoneal solid organ or within intra-abdominal lymphoid tissue. Organisms spread from this purulent focus through the capsule of the organ or lymphoid tissue and enter the peritoneal cavity, with the subsequent development of peritonitis. The intra-abdominal organ or lymphoid tissue may be inoculated

either via bacteremia (e.g., *S. aureus* and renal infection) or as a complication of the normal function of the organ (e.g., *E. coli* and renal infection or *Yersinia* and mesenteric adenitis).[13,38,44]

PERITONITIS AND IMPLANTED DEVICES

Peritonitis is the most significant infectious complication of long-term peritoneal dialysis. Contamination of the dialysis tubing, migration of skin flora from the exit site, or contamination of the dialysate may lead to peritonitis in patients undergoing continuous ambulatory peritoneal dialysis (CAPD). In each instance, a single pathogen usually is isolated.

Gram-positive organisms, coagulase-negative staphylococci, and *S. aureus* account for 30 to 45 percent of peritonitis episodes in children undergoing CAPD. Of CAPD-associated peritonitis episodes, 20 to 30 percent are caused by Enterobacteriaceae.[27] In these instances, contamination of the catheter site with fecal material most often occurs in young children who wear diapers and children with incontinence, an open urogenital sinus, or nephrostomy tubes. The waterborne pathogens *Pseudomonas* and *Acinetobacter* account for 6 percent and 4 percent, respectively, of peritonitis episodes in children receiving CAPD. *Pseudomonas* peritonitis is especially difficult to treat with the dialysis catheter in situ and may recur despite administration of appropriate antimicrobial therapy.[27]

Fungal peritonitis is another complication of CAPD that is difficult to treat successfully without removal of the catheter. Although fungal pathogens have accounted for only 2 percent of peritonitis episodes in children undergoing CAPD, this problem is occurring more commonly.* Most patients with fungal peritonitis have had previous episodes of bacterial peritonitis and antibiotic therapy. The most common fungal pathogens are *Candida* spp.[26,27]; however, rare fungi, such as *Curvularia* spp.,[15] *Fusarium* spp.,[27] *Trichosporon asahii*,[50] and *Aspergillus* spp.,[27] have been reported.[58,79] Other rare causes of CAPD-associated peritonitis include *Mycobacterium fortuitum* and *Mycobacterium chelonae*.[80]

Intra-abdominal infectious complications develop on average in less than 5 percent of infants and children who undergo ventriculoperitoneal shunt placement or revision for hydrocephalus.[57,65,71] Peritonitis, peritoneal pseudocyst, or perforation of the bowel by the abdominal catheter rarely occurs in children with such shunts.† Cerebrospinal fluid (CSF) in the peritoneal cavity may be seeded during transient bacteremia or a febrile illness or after abdominal trauma. In addition, peritonitis may develop as a complication of infection within the ventricles being drained[71] as organisms descend into the peritoneal cavity via the distal tubing.

A peritoneal pseudocyst containing CSF is the most common manifestation of peritoneal inflammation in patients with ventriculoperitoneal shunts. These patients often have a history of symptoms compatible with a shunt infection before the formation of a pseudocyst and may have signs of peritoneal inflammation and a palpable abdominal mass. The microbial etiology of ventriculoperitoneal shunt–associated peritonitis varies and reflects the pathogenesis of infection. Infections occurring within months of surgery often are caused by skin flora, *Staphylococcus epidermidis*, other coagulase-negative staphylococci, and *S. aureus*.[31,62] The microbiology of late shunt-associated peritonitis is similar to that of spontaneous bacterial peritonitis and may include gram-negative enteric organisms and gram-positive cocci.[62] Peritonitis caused by colonic flora also rarely has been associated with bowel perforation by the distal end of the ventriculoperitoneal shunt.[35,62,69]

CLINICAL MANIFESTATIONS

The initial signs and symptoms of primary bacterial peritonitis include nausea, vomiting, diarrhea, and diffuse abdominal pain.[39,42,43] These signs and symptoms are similar to those of secondary peritonitis caused by a ruptured appendix.

Rupture of the appendix is the most common cause of secondary peritonitis in children; the initial symptoms of anorexia, vomiting, and localized abdominal pain frequently precede the signs and symptoms of diffuse peritoneal inflammation. In primary and secondary peritonitis, patients typically lie very still because any movement exacerbates the abdominal pain. Physical findings include fever, tachycardia, abdominal distention, hypoactive bowel sounds, abdominal tenderness, rebound tenderness, abdominal wall rigidity, and tenderness on rectal or vaginal examination. Peritoneal inflammation is associated with an increase in splanchnic blood flow, capillary permeability, and a shift of fluid into the peritoneal space, which may lead to intravascular hypovolemia and shock, in addition to systemic absorption of endotoxin and bacteria.[48]

Fever and abdominal pain in any child undergoing peritoneal dialysis should be evaluated carefully. Turbid dialysate fluid raises the suspicion of CAPD-associated peritonitis. Similarly, symptomatic children with ventriculoperitoneal shunts should be evaluated for shunt-associated peritonitis.[63,65,71,83] In a retrospective report of 19 children with ventriculoperitoneal shunts and peritonitis, Reynolds and associates[63] noted that fever and abdominal pain were the most common symptoms in 14 of their patients. Stamos and colleagues[71] found that fever, lethargy, nausea, and vomiting were the most frequently reported symptoms in a review of 23 children with gram-negative infection of ventriculoperitoneal shunts.

Primary tuberculous peritonitis usually is gradual in onset and associated with weight loss, malaise, and night sweats.[36,37,39,67] The degree of tenderness is less than that present with acute pyogenic peritonitis and may be nonexistent. Palpation of the abdomen may reveal an extensive, irregular collection of masses, often described as "doughy," caused by widespread granulomatous inflammation.[36,39]

*References 15, 26, 27, 50, 58, 79.
†References 5, 31, 35, 62, 63, 65, 69, 75.

DIAGNOSIS

Laboratory findings in a child with peritonitis often are nonspecific. The peripheral white blood cell count usually is elevated (16,000 to ≥25,000 cells/mm^3), with a predominance of polymorphonuclear leukocytes and an increase in immature forms.[39] The hematocrit may be elevated because of dehydration and hemoconcentration. Mild pyuria is noted occasionally because of irritation of the urinary bladder or ureters.

Diagnostic imaging studies can be useful in evaluating intra-abdominal infections. Upright and lateral decubitus radiographs of the abdomen may show distended adynamic loops of bowel suggestive of ileus and obliteration of the peritoneal fat lines and psoas shadows. Free intraperitoneal air below the diaphragm indicates a ruptured viscus. The presence of a fecalith or right lower quadrant mass may be consistent with appendicitis. Abdominal ultrasonography and CT may reveal an underlying cause of the peritonitis.[49,53]

Analysis of peritoneal fluid aspirate or lavage material may be helpful in differentiating primary from secondary peritonitis. Free air, blood, or bile indicates peritonitis secondary to intestinal perforation. In peritonitis, the leukocyte count in peritoneal fluid usually is greater than 250 to 300 white blood cells/mm^3 and sometimes 3000 to 5000 white blood cells/mm^3, with granulocytes predominating in 80 percent of cases.[39,47,70,73] A total protein content greater than 1 g/dL, a glucose level less than 50 mg/dL, or an elevated lactate dehydrogenase concentration (>25 mg/dL) is consistent with secondary peritonitis.[17,33,39,73]

If a Gram stain of peritoneal fluid shows only gram-positive cocci, primary peritonitis is most likely. The presence of gram-negative bacilli is consistent with primary or secondary peritonitis, but the presence of many different organisms on Gram stain is diagnostic of secondary peritonitis. Bacteremia occurs in 75 percent of patients with primary peritonitis. Specimens of peritoneal fluid and blood should be sent for culture.[39] Similarly, secondary peritonitis also can be associated with bacteremia, suggesting the need for obtaining cultures of blood in addition to peritoneal fluid. Specimens of peritoneal fluid should be processed to optimize the recovery of aerobic and anaerobic organisms, and the use of specific transport tubes or an airless, capped syringe is required.[11,39,70] The wide variety of pathogens isolated from intra-abdominal infections along with the variable antibiotic susceptibility of these pathogens supports taking an aggressive approach to obtaining samples for microbiologic evaluation.

A child undergoing CAPD who is suspected of having peritonitis should have dialysate sent for cell count, Gram stain, and culture for bacterial, mycobacterial, and fungal pathogens. If a child with a ventriculoperitoneal shunt is suspected of having peritonitis, CSF from the proximal portion of the shunt should be sent for culture, cell count, and determination of glucose and protein levels in addition to Gram stain and culture of peritoneal fluid.[31] Abdominal imaging by ultrasonography or CT is useful in identifying a peritoneal pseudocyst and the location of distal tubing.

DIFFERENTIAL DIAGNOSIS

Other infectious diseases that may mimic primary or secondary bacterial peritonitis include mesenteric adenitis, gastroenteritis, hepatitis, streptococcal pharyngitis, lower lobe pneumonia, pyelonephritis, and pelvic inflammatory disease. Noninfectious diseases to be considered in the differential diagnosis are pancreatitis, diabetic ketoacidosis, Henoch-Schönlein purpura, ovarian torsion, sickle-cell pain crisis, and lead poisoning.[53]

TREATMENT

Optimal management of peritonitis involves prompt and aggressive physiologic support, surgical consultation, and antimicrobial therapy. Correction of fluid and electrolyte imbalances and hemodynamic stabilization should be initiated as soon as the diagnosis of peritonitis is suspected. Spontaneous bacterial peritonitis usually is managed medically, unless the diagnosis is uncertain, in which case exploratory laparotomy or laparoscopy is performed. Before resistant strains of *S. pneumoniae* emerged, primary peritonitis in children was treated with aqueous penicillin G.[17,33] Given the increased prevalence of *S. pneumoniae* with reduced susceptibility to penicillin, third-generation cephalosporins such as cefotaxime or ceftriaxone are recommended until susceptibility results are available.[47,74] If primary peritonitis is caused by gram-negative organisms, appropriate empirical therapy includes cefotaxime or ceftriaxone, with or without an aminoglycoside, a carbapenem, ticarcillin-clavulanate, or piperacillin-tazobactam, pending completion of culture and susceptibility testing.

Patients with secondary peritonitis may require either immediate surgery to control the source of contamination and to remove necrotic tissue, blood, and intestinal contents from the peritoneal cavity or a drainage procedure if a limited number of large abscesses can be shown.[45,49,54,70,82] In cases of phlegmon, or extensive inflammatory edema, surgery usually is not performed acutely because of the child's unstable metabolic state and friable intra-abdominal tissues. Surgery is delayed for several hours or weeks to allow the inflammation to resolve. Surgery also may be postponed indefinitely.[6,14,59,77]

Empirical antimicrobial therapy for secondary peritonitis should have activity against anaerobes, especially the *B. fragilis* group, and enteric gram-negative aerobes.[7] Although controversial, some regimens also include an antibiotic effective against enterococci. The gold standard for antimicrobial therapy historically has been clindamycin or metronidazole, gentamicin, and ampicillin.* Alternative efficacious regimens, as single or combination therapy, include aztreonam, cefotaxime, cefoxitin, imipenem-cilastatin, meropenem, piperacillin-tazobactam, and ticarcillin-clavulanate.† Rates of resistance to cefoxitin and clindamycin among the *B. fragilis* group have increased and are reported to be 49 percent;

*References 7, 11, 28, 45, 48, 54, 64, 70.
†References 7, 9, 32, 45, 48, 51, 54, 76, 82.

therefore, metronidazole is now recommended and in some institutions alternative regimens are used routinely.[2,48,70] Therapy for secondary peritonitis that is a health care–associated infection should be selected based on local antimicrobial susceptibility patterns at that institution.[70]

Other studies have examined the use of a single broad-spectrum antibiotic, which allows a portion of the therapy to be delivered less expensively on an outpatient basis. Fishman and coworkers[28] prospectively evaluated the clinical outcomes of 150 children with perforated appendicitis treated postoperatively with a 10-day course of piperacillin-tazobactam. They compared the outcome with that of historical controls treated with a 10-day course of ampicillin, gentamicin, and clindamycin. Rates of postoperative infectious complications were similar in both groups. Bradley and colleagues[8] prospectively identified 87 children with complicated appendicitis in five pediatric centers, also comparing costs and outcomes with historical controls. Although inpatient treatment courses were reduced by an average of 42 percent in meropenem-treated children, outcome measures were equivalent to those of historical controls.

Table 53-2 summarizes randomized trials of monotherapy versus combination therapy for ruptured appendicitis in children. Although no differences in outcome were observed, the potential of emerging resistance to broad-spectrum agents versus the convenience of monotherapy must be considered and balanced against the possible decreased risk for developing nosocomial infection among children who can receive a substantial component of parenteral therapy in the home.[40] Goldin and colleagues[32] retrospectively compared the use of triple antibiotic therapy versus monotherapy in a cohort of children with perforated appendicitis and found that single-agent antibiotic therapy in the treatment of perforated appendicitis was at least equal in efficacy to the traditional aminoglycoside-based combination therapy. The potential benefits of a single-agent regimen are reduced length of stay and pharmacy and hospital charges.

Empirical antibiotic treatment of CAPD-associated peritonitis should be effective against gram-positive and gram-negative organisms until culture results are available. Intraperitoneal antibiotics, with or without concomitant intravenous antibiotics, achieve adequate serum and dialysate concentrations. Vancomycin is used for empirical therapy for gram-positive infections, but if staphylococcal organisms are susceptible to β-lactam agents, treatment with cefazolin is effective.[27] Aminoglycosides (gentamicin or tobramycin) or cephalosporins are used for gram-negative infections; however, because most intraperitoneal antibiotics are absorbed into the systemic circulation, serum aminoglycoside or vancomycin concentrations should be monitored for possible toxicity. Therapy for fungal peritonitis usually is intravenous amphotericin B, although successful use of fluconazole or intraperitoneal amphotericin B has been reported.[27,58] Indications for removal of a dialysis catheter include persistent infection with *S. aureus* or *Pseudomonas*, tunnel infection, or fungal peritonitis.[27]

Treatment of peritonitis associated with ventriculoperitoneal shunts usually requires externalization of the distal end of the catheter in addition to institution of antibiotic therapy.[31] Empirical antibiotic therapy should include an antistaphylococcal agent active against coagulase-positive and coagulase-negative staphylococci. Coagulase-negative staphylococci are a common cause of ventriculoperitoneal shunt infection; vancomycin should be administered pending culture and susceptibility results. If Gram stain of ventricular CSF or peritoneal fluid reveals gram-negative organisms, cefotaxime, ceftriaxone, ceftazidime, or meropenem should be added.[5,63]

The duration of antibiotic therapy for peritonitis should be dictated by the clinical course of the patient because no single regimen or treatment course is accepted universally.[39,70] Indicators of sufficient therapy include resolution of fever and abdominal pain and return of the leukocyte and differential counts to normal.[39,54,70,72] Primary peritonitis caused by streptococci is treated successfully with a 10- to 14-day course of antibiotics.[17,39] Primary peritonitis with gram-negative organisms may require 10 days to 3 weeks of antibiotic treatment.[17] The duration of therapy for secondary peritonitis after adequate surgery usually is 5 to 10 days, but it depends on the clinical response to therapy.[39,54,70,72] Short-course

therapy for 5 days has been shown to be efficacious in some patients,[39,54] but longer courses are required if fever persists or abdominal signs and symptoms are present. Standard therapy for tuberculous peritonitis consists of a minimum of two antituberculous drugs. As with other forms of extrapulmonary tuberculosis in children, empirical therapy with isoniazid, rifampin, and pyrazinamide is advised pending culture and susceptibility results. Although *M. bovis* is resistant to pyrazinamide, most strains are susceptible to isoniazid, rifampin, and ethambutol.

COMPLICATIONS

Acute complications associated with peritonitis include septic shock, adult respiratory distress syndrome, septic thrombophlebitis of the portal vein, acute renal failure, and multiple-organ system failure.[48] Postoperative complications include wound infection, adhesions, bowel obstruction, formation of a fistula, and formation of an intra-abdominal or retroperitoneal abscess.

Recurrent peritonitis (tertiary peritonitis) is an entity described as occurring late in the course of therapy for secondary peritonitis.[39,46,70,82] Patients with this condition continue to have symptoms despite receiving appropriate antimicrobial therapy, and peritoneal fluid reveals persistent inflammation. Bacterial cultures often are negative or may yield an organism of low virulence. Multiple-organ system failure and a poor outcome frequently are associated with tertiary peritonitis. The mechanism of ongoing peritoneal inflammation is unknown; however, some investigators have proposed that immunoregulatory dysfunction and poor nutrition are contributing factors.

INTRA-ABDOMINAL ABSCESS

Intra-abdominal abscesses often are categorized as intraperitoneal, visceral, or retroperitoneal (see Chapter 54).[4,10] In children, intraperitoneal abscesses are most common. The most common underlying conditions associated with an intra-abdominal abscess in children are appendicitis and trauma.[10,53] Reviews of gangrenous or perforated appendicitis in children indicate that 2 to 20 percent of cases are complicated by the formation of an abscess.[54,64]

Two basic mechanisms exist for the development of an intraperitoneal abscess. In the first mechanism, diffuse peritonitis may cause loculations of purulent material to form in the areas anatomically most dependent—typically the pelvic, subphrenic, and paracolic regions (see Fig. 53-1). The second mode of formation of an abscess involves a localized focus related to contiguous disease or injury in which host defenses and the inflammatory response prevent diffuse spread and peritonitis.[4] The microbiology of intraperitoneal abscesses is polymicrobial and reflects that of the intestinal flora. In a review of intra-abdominal abscess in 36 children, Brook[10,11] noted that the predominant organisms were the *B. fragilis* group, *Peptostreptococcus*, *E. coli*, and other Enterobacteriaceae.

The most common sites of visceral abscess in children are the liver (see Chapter 49), pancreas, and spleen. Underlying conditions that may lead to the development of a pancreatic abscess include pancreatic injury, pancreatitis, and biliary obstruction. Pancreatitis or surgical or accidental injury to the pancreas causes the release of pancreatic enzymes and focal necrosis.[29] Reflux of contaminated bile into the pancreatic duct is hypothesized to be the mechanism by which enteric organisms gain access to the injured pancreas and proliferate. A pancreatic abscess usually is a polymicrobial infection caused by aerobic (*E. coli*, *Klebsiella pneumoniae*, group D streptococci) or anaerobic (peptostreptococci, *B. fragilis* group) organisms that inhabit the gastrointestinal tract. Rare instances of *S. aureus* pancreatic abscess occur as a result of bacteremia.[12,13]

Splenic abscesses are unusual findings in infants and children. Before the 1970s, most reports involved solitary pyogenic abscesses. Since then, the number of reports of multiple splenic abscesses has increased.[16,41,60] Splenic abscess usually is associated with one of five underlying conditions: endocarditis, injury, hemoglobinopathy, immunodeficiency, or adjacent infection. Given the filtering function of the spleen, an abscess can form as a result of any metastatic hematogenous infection, such as endocarditis. Although rare, splenic abscess can be a delayed complication of the nonoperative management of splenic injuries. Splenic infarcts associated with hemoglobinopathies such as sickle-cell disease may become secondarily infected and form an abscess.[16] Immunodeficiency, such as malignancy or acquired immunodeficiency syndrome, is another significant risk factor for the development of multiple splenic abscesses.[41,55,60]

Rarely, infection or disease in a contiguous focus may extend to the spleen. In a review of 56 children with splenic abscesses, 7 (12.5%) were cryptogenic with no apparent cause.[41] In most instances, a single pathogen is isolated, with *S. aureus*, streptococci, *E. coli*, and *Salmonella* spp. being the most common. Fungi, most often *Candida* spp., have been isolated from splenic abscesses primarily in immunocompromised hosts.[41,55,60]

CLINICAL MANIFESTATIONS

The typical clinical features of an intra-abdominal abscess include fever, abdominal pain, and tenderness over the involved area. Subphrenic abscesses also may be

manifested as referred pain or pulmonary or pleuritic symptoms. Pancreatic abscess may be associated with a palpable epigastric mass and elevated serum lipase and amylase.[12] Splenomegaly or a splenic mass may be noted in approximately half of patients with splenic abscesses.[41] In postoperative patients, persistence of abdominal symptoms or fever warrants evaluation for an intraperitoneal abscess.[3] Leukocytosis (20,000 to 50,000 cells/mm^3) frequently is present in children with an intra-abdominal abscess.[3,39]

DIAGNOSIS

Imaging studies are helpful in diagnosing an intra-abdominal abscess. Plain radiographs are useful as an initial procedure and may show an extraintestinal air–fluid level, right lower quadrant mass, or localized ileus.[1] Chest radiographs should be obtained because subphrenic abscesses often are associated with a pleural effusion. In a series of 27 children with splenic abscesses, chest radiographs were abnormal in 20 cases, with the most common findings being left pleural effusion and an elevated left hemidiaphragm.[41] Ultrasonography is a useful noninvasive technique that can detect abdominal and pelvic abscesses. The quality of the images depends on the examiner, however. In addition, conditions such as ileus, postoperative drains, or dressings may hinder ultrasound detection of an abscess.[1,49,52] CT is the most sensitive tool for detecting an intra-abdominal abscess, and it provides good anatomic resolution. Disadvantages of CT are the radiation and, if used, exposure to intravenous, oral, or rectal contrast material.[1,49,52]

Although more recent experience with the use of magnetic resonance imaging for detecting an intraperitoneal abscess has been described in the literature,[56] this modality should be considered in children only when an abscess may not be detected more easily by other methods or in patients who should not have exposure to radiation.[56] Gallium scanning is a sensitive technique for diagnosing an abscess, but it is nonspecific, particularly in the abdomen.[1]

TREATMENT

Management of an intra-abdominal abscess includes physiologic and nutritional support, antimicrobial therapy, and drainage. After blood cultures have been obtained, empirical antibiotic therapy should be instituted with agents effective against anaerobes, Enterobacteriaceae, and other enteric flora as discussed earlier for peritonitis. Antibiotic therapy usually is begun before surgery is done to minimize any complications of bacteremia during the procedure. Abscess material should be obtained for culture of aerobic, anaerobic, fungal, and mycobacterial pathogens. Effective surgical management depends on accurate localization of the abscess, discrimination between single and multiple abscesses, and early and adequate drainage.[3,4,48] Traditional therapy for intraperitoneal abscesses has relied on open surgical drainage, although drainage of intraperitoneal abscesses percutaneously under ultrasound or CT guidance now is used often.*

In instances of multiple intraperitoneal abscesses or if the source of peritoneal contamination has not been controlled, laparotomy is indicated.[48] Pancreatic abscesses require intensive surgical and medical therapy. Antimicrobial therapy for mixed aerobic and anaerobic infection is suggested,[12] but splenectomy remains the definitive treatment of bacterial splenic abscesses. In selected patients, percutaneous drainage or splenotomy has the advantage of preserving splenic function, however.[41,55,60] Multiple small splenic abscesses and fungal lesions generally are treated medically.[41] Antibiotic therapy for a pyogenic splenic abscess should be guided by the pathogens associated with the child's underlying condition. Therapy should include antibiotics effective against *S. aureus*, streptococci, and gram-negative enteric bacilli. Specific therapy should be revised after culture and susceptibility results are available.

COMPLICATIONS

Intraperitoneal and visceral abscesses, if not adequately drained, may be associated with significant complications, including ongoing spread of the infectious process and, for splenic or pancreatic abscesses, a high mortality rate. Fistula formation, adhesions, and bowel obstruction may be late complications of intra-abdominal infection.

CHAPTER 54

Retroperitoneal Infections

Alice Pong • John S. Bradley

Retroperitoneal infections consist primarily of suppurative bacterial infections that originate within the retroperitoneal structures or as an extension from another primary site with systemic spread. In children, these infections are much less common than are intra-abdominal infections; however, they can lead to significant morbidity if missed. Making a diagnosis can be difficult because symptoms often are indolent and poorly localized.

Several retroperitoneal spaces exist; each may harbor a localized infection.

The retroperitoneal structures are separated from the intra-abdominal organs by the posterior peritoneal fascia (Fig. 54-1). Structures posterior to this fascia layer, in the anterior retroperitoneal space, include the duodenum, pancreas, and parts of the colon. The kidneys and ureters are encased further by the renal fascia. The iliopsoas and psoas muscles lie at the posterior aspect of the retroperitoneal space and are separated from the other retroperitoneal structures by the transversalis fascia. Pelvic structures, including the bladder, uterus, and rectum, that lie inferior to the pelvic peritoneum constitute the pelvic portion of the retroperitoneal space. The fascial layers limit the spread of retroperitoneal infections. However, the deep location can be difficult to assess by physical examination.

ETIOLOGY AND PATHOGENESIS

Retroperitoneal infections in children arise in numerous anatomic structures. Brook[7] reviewed cases of retroperitoneal infections from five U.S. hospitals from 1974 to 1994. Forty-one children were identified. Twenty-one had infections in the anterior retroperitoneal space related to the pancreas (4) and intestines (13), 6 had perinephric abscesses, 7 had iliopsoas abscesses, and 7 had pelvic retroperitoneal abscesses.

Primary infection of the retroperitoneal space within the renal fascia can be hematogenous in origin or complicate an ascending urinary tract infection. Within the anterior retroperitoneal space, secondary infections occur as a direct extension from gastrointestinal perforations such as ruptured appendices or those related to Crohn disease.[7,24,26] Greenstein and associates reported retroperitoneal abscesses in 12 of 231 patients with Crohn disease.[24] Retroperitoneal infections, particularly of the pelvic space, can also develop secondary to primary infections of the vertebral spine, pelvic bones, and sacroiliac joint.[27,49,52] Suppurative iliac or retroperitoneal lymph nodes are another source of retroperitoneal infections. Prior surgery has been reported as a predisposing factor in perinephric abscesses[8,20] and in vascular grafts in adults.[10] Pancreatic abscesses are seen more commonly in adult patients and are associated with underlying biliary tract disease, alcoholism, surgery, and trauma.[9] Acute pancreatitis occurs less frequently in children than in adults, but when it occurs infections are often implicated.[29,55]

Infections of the perinephric retroperitoneal space include those involving the kidney and adrenal glands. Perinephric abscesses can result from bacteremic inoculation of renal tissue or as a consequence of an ascending urinary tract infection. Nephronia (i.e., focal renal cellulitis, focal bacterial nephritis) is thought to be an intermediate stage of renal infection between pyelonephritis and renal abscess, resulting from an ascending infection of the urinary tract.[13] Adrenal abscesses are reported more frequently in neonates than in older children and are suspected to be related to adrenal hemorrhages that become secondarily infected.[41]

Iliopsoas abscesses may be a consequence of hematogenous seeding of the muscle, with trauma as a predisposing factor (Fig. 54-2).[26,48] Although primary infection occurs most commonly,[6] the iliopsoas muscle extends from the ribs and lumbar vertebrae to its insertion on the femur and is exposed to the risk of extension of infection from numerous adjacent structures. Psoas abscesses have developed as a consequence of vertebral infections, intestinal perforations, and genitourinary sources.[26,30] Neonatal iliopsoas abscesses have also been reported and patients present with symptoms similar to that of a septic hip.[18,21,44]

Complications of retroperitoneal abscesses include both rupture into the intraperitoneal space and extension of the infection along fascial planes to adjacent muscles that extend from origins in the pelvis and trunk to insertion sites on the femur. Rupture into the thoracic cavity also has been reported.[1] Other reported complications include pneumonia, recurrent abscess, renal failure, and venous and arterial thrombosis.[15]

MICROBIOLOGY

The microbiology of retroperitoneal infections is determined by the source of the infection and the retroperitoneal compartment involved. Most primary infections thought to result from bacteremia are caused by *Staphylococcus aureus*, including methicillin-resistant *S. aureus* (MRSA).[45] Secondary infection related to the

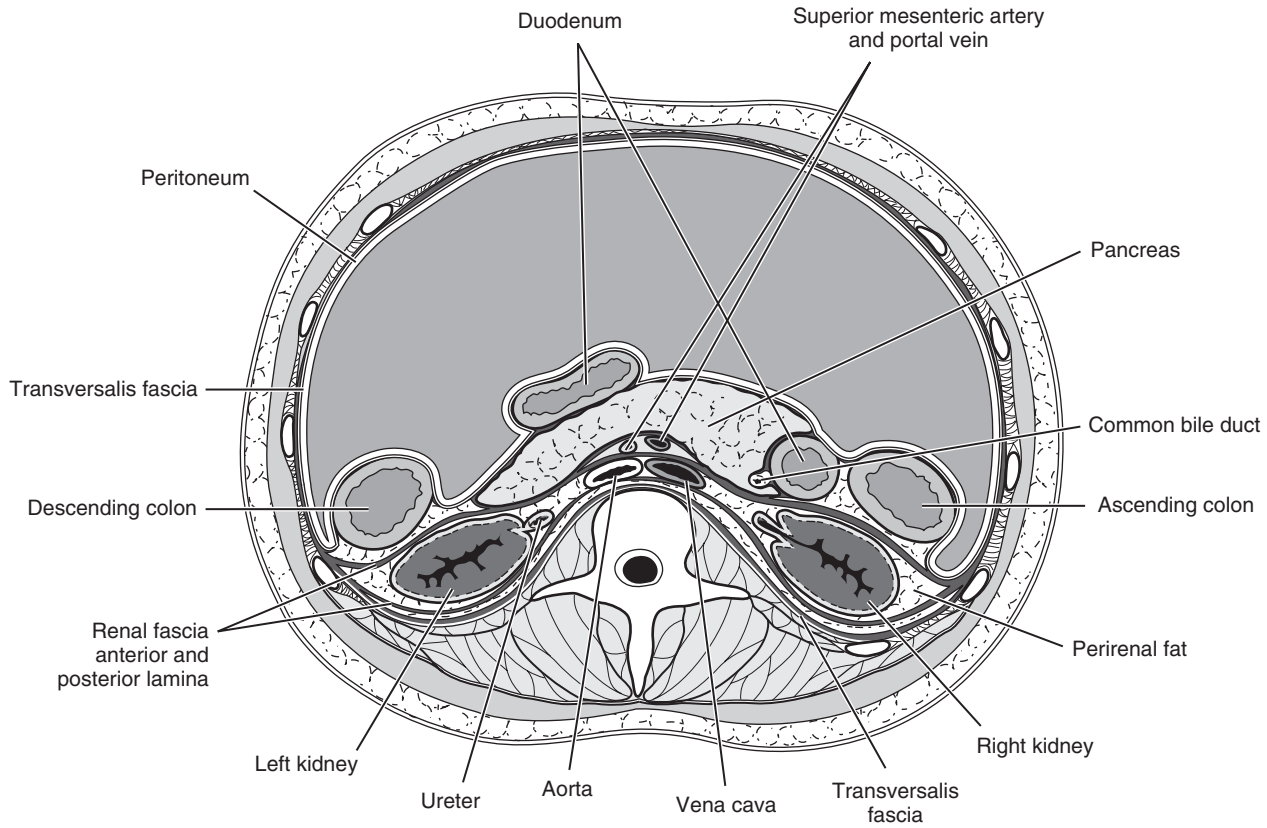

FIGURE 54-1 ■ Cross section of abdomen at L2 shows the structures within the retroperitoneal space. (From Altemeier WA, Alexander JW. Retroperitoneal abscess. *Arch Surg* 1961;**83**:515, with permission.)

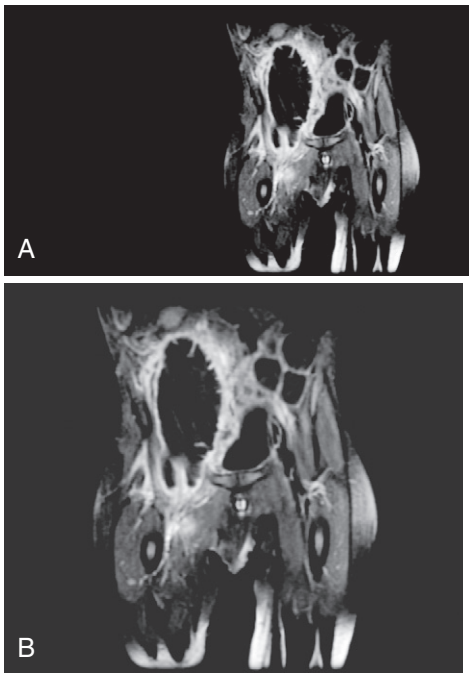

FIGURE 54-2 ■ Coronal postcontrast **(A)** and axial postcontrast **(B)** MR images of a large iliopsoas abscess.

gastrointestinal tract is caused by mixed bowel flora including *Escherichia coli*, other gram-negative enteric bacteria, *Pseudomonas* spp., and gastrointestinal anaerobes, particularly *Bacteroides fragilis* and *Peptostreptococcus*.[7] Most infections in the anterior retroperitoneal space are associated with a gastrointestinal source and may be polymicrobial. *Actinomyces* infections, although more commonly seen in the cervicofacial area, can also present as retroperitoneal infections.[4,35]

Ascending infections from the urinary tract usually are caused by *E. coli;* however, perinephric abscesses also are reported as a complication of renal infection caused by *S. aureus*, group B *Streptococcus*, and *Salmonella*.[20,56,57]

S. aureus is the leading pathogen isolated in iliopsoas abscesses unless the infection is secondary to erosion of a primary gastrointestinal focus. In that situation, gram-negative enteric bacteria and anaerobes are more likely to be the causative agents.[6,48] Retroperitoneal necrotizing fasciitis from group A *Streptococcus* has also been reported.[17]

Tuberculosis caused by *Mycobacterium tuberculosis* or *Mycobacterium bovis* may involve the retroperitoneal space as an extension of vertebral tuberculous osteomyelitis.[1,19,30] Abdominal tuberculosis usually manifests as an intraperitoneal infection but can produce retroperitoneal adenopathy.

The most common infectious agents associated with acute pancreatitis are viral pathogens including adenovirus, group B coxsackieviruses, mumps, and hepatitis

viruses (A, B, E).* Varicella, herpes simplex virus, cytomegalovirus, Epstein-Barr virus, and rotavirus have also been reported as associated infections in patients with acute pancreatitis.[16,22,33,46,47] Bacterial pathogens including *Salmonella* and *Mycoplasma*[39,42,46] are less frequently associated with pancreatitis. *Ascaris lumbricoides* can cause acute pancreatitis via obstruction of the common bile duct or other intrahepatic and pancreatic ducts.[31,46]

CLINICAL MANIFESTATIONS

Children with retroperitoneal infections present clinically in a variety of ways, ranging from nonspecific fever to overwhelming sepsis. The most common clinical symptoms associated with retroperitoneal infections include fever and pain in the hip, back, and abdomen.[15,37] Psoas abscesses often manifest as the child limping or refusing to walk.[6] Neonates with a retroperitoneal abscess may present with an abdominal mass.[50] In children, acute pancreatitis presents most commonly as abdominal pain and vomiting, rather than back pain.[25,29,55] Symptoms associated with retroperitoneal infections can be vague, and pain is not well localized. Patients often have been evaluated previously for fevers and have been treated with antibiotics before a diagnosis has been made.[6,32,49] A delay in the diagnosis is not uncommon.

DIFFERENTIAL DIAGNOSIS

Retroperitoneal infections can be confused with a variety of other infections. Limp and fever caused by pyogenic arthritis of the hip and infection of the sacroiliac joint and pelvic bones are more common than retroperitoneal infections. Abdominal pain and fever are more frequently seen in patients with intra-abdominal infections, including appendicitis and intra-abdominal abscesses. Trauma and malignant disease are more frequent causes of retroperitoneal masses compared with infectious causes and should be considered.

SPECIFIC DIAGNOSIS

Laboratory tests often are nonspecific and of minimal benefit. Sedimentation rates and leukocyte counts often are elevated.[6,7,48,49] Pancreatic enzymes including amylase and lipase are usually elevated with acute pancreatitis. Pyuria often is absent in children with perinephric and renal abscesses, and the urine culture result may be negative.[8,20,54,56] However, in patients with nephronia, pyuria and positive urine cultures are more likely.[13,32] Blood cultures may be helpful in identifying a bacterial pathogen. Brook[7] reported that 40 percent of blood cultures were positive for the same organism isolated from abscesses in children with retroperitoneal infections who had blood cultures collected. For children with psoas abscesses, Santaella and colleagues[48] reported that 71 percent of blood cultures were positive.

Imaging studies are the most useful diagnostic tools. Ultrasonography can be used to diagnose perinephric infections[8,54] and has been used to diagnose abscesses of the iliopsoas muscle.[26] Computed tomography (CT) with contrast enhancement can be the most helpful[12,15,48] because of superior delineation of organ involvement and the extent of infection. CT also can provide clues about the primary focus of the infection, thereby helping to guide empirical antibiotic therapy. Abscess fluid is seen on CT as areas of low attenuation, often with an enhancing rim.[12,34,56] Percutaneous drainage and biopsy of the lesions may also be accomplished with CT. Magnetic resonance imaging (MRI) offers the advantage over CT of superior visualization of inflamed bone and muscle tissue, although calcifications may not be as well identified.[43] Although alternative diagnoses also can be evaluated with CT,[51] hematomas and certain tumors may not be easily distinguished radiographically from infection. These noninfectious entities may be better identified by MRI. Decreased radiation exposure is an additional advantage of MRI.

TREATMENT

Percutaneous or open surgical drainage should be considered for all retroperitoneal infections for both diagnostic and treatment purposes. Culture of the aspirated fluid for aerobic and anaerobic bacteria, mycobacteria, and fungi is vital to selecting appropriate antimicrobial therapy. Reports of percutaneous drainage of deep tissue abscesses are increasing.[6,30] These procedures usually are performed with ultrasound or CT guidance. Treatment of patients with antibiotics alone without surgical drainage may not be effective, particularly in cases involving larger abscesses.[1,12]

Initial antimicrobial therapy for retroperitoneal infections should be directed by the presumed source of the infection, with definitive therapy guided by microbiologic culture results. Infections related to gastrointestinal perforation should include coverage directed primarily against enteric gram-negative bacteria and gastrointestinal anaerobes such as β-lactamase–producing *B. fragilis*. Coverage for *Pseudomonas* and *Enterococcus* spp. also should be considered. Historically, antibiotic combinations such as ampicillin for enterococcus, metronidazole or clindamycin for anaerobes, and a third-generation cephalosporin or aminoglycoside for gram-negative bacteria have been used. However, carbapenems such as meropenem, imipenem, or ertapenem as single agents may be more cost effective, particularly if any outpatient antibiotic therapy is being considered. The β-lactam and β-lactamase inhibitor combinations (e.g., ticarcillin-clavulanate, piperacillin-tazobactam), with or without an aminoglycoside, are also likely to be effective.

Infections of renal origin, usually caused by *E. coli* or other gram-negative enteric organisms, can be treated with extended-spectrum cephalosporins such as ceftriaxone or, if abscesses have been drained successfully, with aminoglycosides such as gentamicin or tobramycin. The activity of aminoglycosides may be compromised by the acidic environment of abscess cavities and may lead to

*References 3, 14, 25, 28, 40, 46, 53.

clinical failures despite in vitro susceptibility of the organism.[11] Increasingly, resistance to ampicillin is seen in *E. coli*,[2,5] rendering it unreliable for empirical use in severe urinary tract infections. *Pseudomonas* is not an uncommon pathogen in children with recurrent infections caused by anatomic genitourinary abnormalities.[2] *Pseudomonas* spp. usually are resistant to ceftriaxone; extended-spectrum cephalosporins such as ceftazidime or cefepime, or a carbapenem, may be needed. Urine or abscess culture and susceptibility results help to focus the antibiotic choice to the agent with the most narrow spectrum of effectiveness.

Psoas abscesses and primary perinephric abscesses caused by *S. aureus* should be treated with an antistaphylococcal agent such as nafcillin (or oxacillin or methicillin) or a first-generation cephalosporin such as cefazolin. The prevalence of community-acquired methicillin-resistant *S. aureus* (CA-MRSA) has increased significantly as a soft tissue pathogen, particularly in children.[23,38] Vancomycin or clindamycin should be considered as empirical therapy for serious infections in areas with high rates of CA-MRSA (more than 5 percent of all invasive *S. aureus* infections) until culture results are available. These agents also may be effective in treating the patient who is unable to tolerate penicillin or cephalosporin antibiotics.

Infections originating in the vertebrae are most often caused by *S. aureus* or may result from tuberculosis. Empirical antistaphylococcal therapy can be started, but culture and histologic examination of tissue are needed to direct appropriate therapy. For the child with risk factors for tuberculosis, a positive tuberculin skin test or interferon-γ release assay, and a negative Gram stain result, empirical therapy with three or four antituberculous antibiotics should be considered. A chest radiograph should be obtained to look for evidence of pulmonary tuberculosis.

After adequate drainage is achieved, the duration of antimicrobial therapy depends on several factors, including the organism, the site and extent of infection, and clinical improvement. Most drained retroperitoneal bacterial abscesses of renal or muscle origin are treated for 2 to 3 weeks with initial parenteral and follow-up oral antibiotics. Infections involving bone may require 6 to 8 weeks or longer, depending on how quickly the infection responds to treatment. Radiographic studies, erythrocyte sedimentation rate, and C-reactive protein measurement can be helpful to monitor recovery. Tuberculous infections are treated for 6 to 12 months, depending on the presence of bone involvement. *Actinomyces* infection can be difficult to treat because of lack of susceptibility to many antibiotics and the need for prolonged courses of antibiotic therapy, preferentially with penicillin.

Treatment of pancreatitis is primarily supportive with elimination of enteral feedings and pain control. There have been some reports of adenovirus treatment with cidofovir, particularly in the bone marrow transplant population.[3,36,58]

PROGNOSIS

Historically, retroperitoneal infections are reported to have high morbidity and mortality rates. However, with modern imaging techniques enabling more timely diagnoses, the overall prognosis is good and most children with no underlying disease recover without sequelae.

SECTION **IX**

MUSCULOSKELETAL INFECTIONS

CHAPTER 55

Osteomyelitis

Paul Krogstad

The term *osteomyelitis* denotes inflammation of bone and marrow but generally implies the presence of infection. Osteomyelitis is considered acute if diagnosed within 2 weeks of the onset of symptoms and is subacute or chronic if symptoms have been present for more than 2 weeks at the time of presentation. Although bacteria are the most common cause, fungi, parasites, and other microorganisms also may cause osteomyelitis. These microorganisms can be introduced into bone in three ways: (1) by direct inoculation, usually traumatic but also during surgery or due to the presence of orthopedic fixation devices; (2) by local invasion from a contiguous focus of infection; and (3) by hematogenous delivery. In children, osteomyelitis is generally of hematogenous origin and occurs in long, tubular bones. Regardless of the route of infection, the goal of treatment is to arrest the infection and limit the extent of the injury to bone.

The incidence of osteomyelitis in normal children has been examined in several populations. Estimates have varied from 1 in 20,000 adolescent girls in New Zealand to 1 in 1,000 Australian Aboriginals.[28,51,90,150] Boys contract the disease 1.2 to 3.7 times more often than do girls.[90,171,202] Osteomyelitis occurs most often in the first 2 decades of life. Approximately 25 percent of children with osteomyelitis are younger than 2 years old, and 50 percent are younger than 5 years old.[91,130,165,226] The incidence is increased in patients with sickle-cell disease and in some other immunocompromised patients (see the section on special populations).

Although cultures fail to identify bacterial pathogens in approximately one fourth to half of all cases of osteomyelitis in children, most microbiologically confirmed infections are caused by single organisms.[8,24,165,175] When polymicrobial infections are encountered, they may reflect the spread of infection from contiguous infectious foci and most often occur in the skull, face, hands, or feet. Distal extremities compromised by vascular insufficiency or immobilized because of peripheral neuropathy also are sites of polymicrobial osteomyelitis.

Gram-positive bacteria are most often identified, especially *Staphylococcus aureus*[91,184,219,224] and *Streptococcus pyogenes;* together they account for 80 to 90 percent or more of cases in most series (Table 55-1). However, *Kingella kingae*, a fastidious gram-negative organism, is increasingly being identified in young children as a cause of osteoarticular infections, including osteomyelitis, diskitis, and septic arthritis. *K. kingae* osteomyelitis has been identified at a frequency equal to *S. pyogenes* in some series,[143,150] and its incidence may have been historically underestimated because of its fastidious growth. Polymerase chain reaction–based studies suggest that it accounts for many cases of culture-negative osteoarticular disease.[239] Reports demonstrating its importance as a cause of osteoarticular infections in young children have come from countries as diverse as Israel, the United States, Australia, Switzerland, and Iceland,* and in two reports *Kingella* infections exceeded those of gram-positive pathogens.[39,42]

Streptococcus pneumoniae has been a frequent cause of osteomyelitis in the past, but protein conjugate vaccines have markedly reduced the frequency of invasive pneumococcal infections, including pneumococcal osteomyelitis. Similarly, *Haemophilus influenzae* used to cause 5 to 8 percent of cases and was found primarily in infants and younger children†; however, cases of *H. influenzae* osteomyelitis are noticeably absent from most recent case series.[8,91,122,170,244]

Even in affluent countries *Salmonella* spp. are occasionally a cause of osteomyelitis in immunocompetent patients, and *Salmonella* spp. are the most common organism found in cases of osteomyelitis in patients with sickle-cell disease (see later).[91,165] Osteomyelitis caused by *Escherichia coli* and other aerobic enteric gram-negative organisms is also seen, generally in neonates and young infants.[238] Osteomyelitis caused by *Pseudomonas aeruginosa* has been associated with injection drug use.[110,137,235]

Although rare in comparison to osteomyelitis caused by aerobic bacteria, four distinct clinical entities of osteomyelitis caused by anaerobic bacteria are recognized: (1) bacteremic seeding of previously normal bones in children and young adults; (2) superinfection of a fracture site already infected with *S. aureus;* (3) indolent (months to years after surgery) infection of a prosthetic device; and (4) contiguous chronic infection,[213] which most often occurs in the skull and the extremities. *Bacteroides* spp. are found most commonly and are associated with paranasal, sinus, or mastoid infection. In most cases, a foul odor is noted when the bone is incised or the focus is opened; trauma often has been an inciting influence.[138]

Osteomyelitis caused by fungi and atypical bacterial pathogens occasionally occurs in children and is discussed in greater detail later.

HEMATOGENOUS OSTEOMYELITIS

Pathogenesis

In long tubular bones, hematogenous osteomyelitis generally begins in the metaphysis, the broad cancellous end of the bone shaft adjacent to the epiphyseal growth plate.

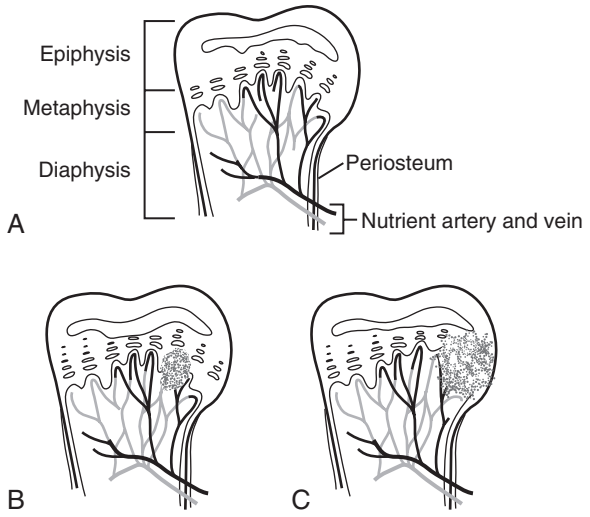

FIGURE 55-1 ■ **A,** The sluggish blood flow in the sinusoidal venous connections located at the metaphyseal-epiphyseal junction predisposes to the development of traumatic thrombosis and infarction. **B,** Bacteremic seeding of the avascular area initiates the infection, which spreads through the Volkmann canals and the haversian systems and causes septic thrombosis. **C,** Infection tends to spread laterally through the cortex and elevates or ruptures through the periosteum.

The cartilaginous epiphyseal growth plate (the physis) is nourished by diffusion of nutrients from a narrow plexus of capillaries fed by the metaphyseal branches of a nutrient artery; these capillaries drain into a large sinusoidal plexus that ultimately joins the large sinusoidal veins in the bone marrow (Fig. 55-1).[108] Trauma or emboli lead to occlusion of the slow-flowing sinusoidal vessels, establishing a nidus for infection. Blood-borne bacteria can seed the poorly perfused area and proliferate.[46,119,221]

The high frequency of *S. aureus* in osteomyelitis may reflect specific pathogenic properties of the organisms, including the ability to adhere to type I collagen of bone fibrils.[35] When *S. aureus* binds to collagen, bacterial replication gives rise to microcolonies surrounded by a glycocalyx.[102] Continued injury, elicited by *S. aureus* exoproducts and the host cellular inflammatory response to the injury, causes the accumulation of exudate under pressure. The pressure compresses blood vessels of bone and produces focal bone necrosis. The low ratio of surface area to mass, combined with the blood vessel anatomy described earlier, interferes with reabsorption of necrotic cortical bone[46,119] and the effectiveness of host defense mechanisms. The very early stages of osteomyelitis may be aborted by administration of appropriate chemotherapy. In the absence of therapy, necrosis of cortical bone and marrow continues. The exudate under pressure is forced through the haversian systems and Volkmann canals and into the cortex (see Fig. 55-1).

Beginning in the late 1990s, community-acquired methicillin-resistant *S. aureus* (CA-MRSA) isolates became a common cause of musculoskeletal infections in the United States and other countries. Most of these CA-MRSA isolates from cases of osteomyelitis carry genes encoding Panton-Valentine leukocidin.[23] Panton-Valentine leukocidin–positive CA-MRSA has been associated frequently with sepsis, venous thrombosis, adjacent myositis, and polyostotic disease, suggesting that this or other factors contribute to the development and severity of hematogenous osteomyelitis.[29,148] However, it is important to note that similar patterns of disease are seen in Panton-Valentine leukocidin–negative organisms[120] and the precise role of this substance in *S. aureus*–associated disease remains unclear.

Clinical Manifestations

The bacteremic phase of hematogenous osteomyelitis may be entirely subclinical and associated only with malaise and low-grade fever, or it may be characterized by severe constitutional symptoms with high fevers (39° to 40°C [102.2° to 104°F]). The subsequent clinical manifestations of osteomyelitis are not related to the severity of initial constitutional signs of infection but are influenced by the age of the child and the etiologic agent (Fig. 55-2).

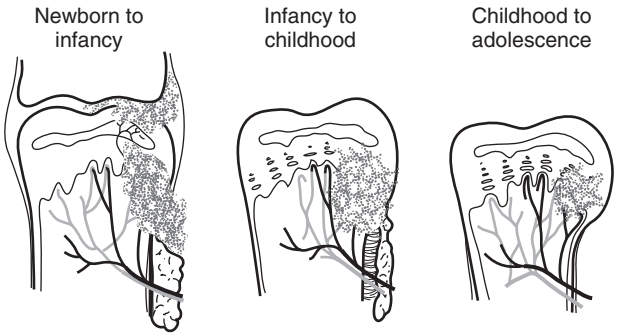

FIGURE 55-2 ■ In young infants and neonates, particularly in the hip where the epiphyseal growth plate is traversed by nutrient vessels terminating in the distal ossification center, septic thrombophlebitis of the nutrient vessels can lead to growth discrepancies. With the capsule of the joint extending to the metaphysis, rupture of the infection through the cortex leads to the development of septic arthritis. Because of the thin cortex and loose periosteum, the osteomyelitis may come to medical attention as a deep soft tissue abscess. In older infants and young children, the thicker cortex and denser periosteum are a greater barrier to infection. Local tenderness from subperiosteal edema or abscess is the rule. In late childhood and adolescence, the lesion is extremely well localized and rarely penetrates the bony cortex. In this age group, invasive procedures, such as windowing or drilling, are necessary to obtain infected material.

In neonates, the thin cortex and loosely attached periosteum are poor barriers to the spread of infection. Consequently, the purulence rapidly ruptures through both of these structures into the contiguous muscle bed. With progression of the infection, the purulent material often dissects the muscle bundles, with the swollen, discolored limb taking the appearance of a sausage. In addition, nutrient metaphyseal capillaries perforate the epiphyseal growth plate in neonates and the capsule of the diarthrodial joints frequently extends to or is slightly distal to the epiphyseal plate. These anatomic characteristics permit an infection arising in the metaphysis to involve the epiphysis and to extend into the adjacent joint cavity.

In older infants, the cortex (see Fig. 55-2) is thicker and the periosteum is slightly more dense. Consequently, the infection spreads less often to the soft tissues of the extremity. Subperiosteal abscess and contiguous edema readily develop, however. The nutrient metaphyseal capillaries in older infants are atrophic, which, although more recently disputed,[172] is thought to decrease the risk of spread of infection into the adjacent joint space. The subperiosteal purulence almost always is at the metaphysis, the area in which the cortex is the thinnest.[99]

In children and adolescents (4 to 16 years old), the metaphyseal cortex is considerably thicker, with a dense, fibrous periosteum. The pathogenesis of the infection is the same in this age group, but the infection rarely ruptures and spreads to the outer cortical lamellae. As a result, the signs and symptoms of osteomyelitis in these older children and adolescents usually are more focal.

A neonate with osteomyelitis usually is irritable and displays evidence of pain when the affected extremity is touched or moved. Pseudoparalysis may occur; and if the disease remains untreated, massive swelling of the extremity may be seen. Obtaining a plain radiograph is particularly valuable in this age group; most of these patients have changes consistent with osteomyelitis on the initial radiograph.[126,158,232] In infants and young children, pain usually is present, as is a limp because osteomyelitis occurs more commonly in the lower extremities. The child usually refuses to use the affected extremity and displays variable constitutional symptoms.

In older children and adolescents, less restriction of function of the extremity is found compared with infants and young children. The point tenderness is circumscribed more sharply and may be found only as a small area of discomfort at rest. This disease most often affects the lower extremities and produces a mild limp. Most commonly, tubular bones are involved, but osteomyelitis occurs throughout the skeleton (Table 55-2). The hallmark of the disease is the focal nature of symptoms; point tenderness and well-localized pain suggest the diagnosis. Percussion of the long bone away from the area of point tenderness often elicits pain at the site of osteomyelitis in older children and adolescents.

Data from reference 165; similar distribution of affected bones has been reported in other reports.[24,91,169]

The clinical features of osteomyelitis are also influenced by the organisms involved. Osteomyelitis caused by CA-MRSA seems to be more complex and severe than are infections caused by methicillin-susceptible *S. aureus* (MSSA). Life-threatening infections caused by CA-MRSA have been reported in adolescents, and polyostotic disease is more common (15% in one more recent series compared with 2% in a large series that preceded the emergence of CA-MRSA).[23,165] Myositis, pyomyositis, intraosseous and subperiosteal abscesses, and septic thrombophlebitis also seem to occur more frequently with CA-MRSA than with MSSA.[8,94,95,148] Osteoarticular infections caused by *Kingella* spp. arise in children younger than 36 months of age and have an indolent course, with limb pain often present for longer than a week before initial medical evaluation is made; complications are largely unknown.[62,143,239,242] Osteomyelitis caused by *H. influenzae* seems to occur primarily in the upper extremities.[68,69,97,211]

Culture-negative osteomyelitis is generally milder than diseases with microbiologically confirmed causes. In one series comparing 45 culture-positive patients with 40 patients with culture-negative osteomyelitis, symptoms were of longer duration and overlying skin changes were seen less frequently in patients with negative disease. Treatment with β-lactams generally was successful and associated with skeletal sequelae in only one case.[77] Whether these features of culture-negative osteomyelitis suggest a more effective host defense, or infection by a less virulent and more fastidious pathogen such as *K. kingae*,[227] remains unclear.

Differential Diagnosis

Infectious osteomyelitis can be confused with many other conditions associated with pain and tenderness in an extremity, including fractures, rheumatic fever, septicemia, septic arthritis, cellulitis, Ewing sarcoma and malignant bone tumors, osteoid osteoma, leukemia, complex regional pain syndrome (reflex neurovascular dystrophy), thrombophlebitis, bone infarction secondary to sickle-cell or Gaucher disease, and toxic synovitis.

Chronic recurrent multifocal osteomyelitis (CRMO) (also known as chronic nonbacterial osteomyelitis) must also be considered in some cases and merits special attention in the differential diagnosis. As originally described by Giedion and coworkers,[87] CRMO is a chronic illness generally characterized by multiple chronic focal, inflammatory lesions in bone with periodic exacerbation and remission, and moderate bone pain.[225] It occurs more commonly in girls younger than 10 years of age. Many of the cases are in children of northern European origin.[19,125] At presentation, about half of patients have fever and virtually all have an increased erythrocyte sedimentation rate (ESR) (or increased C-reactive protein [CRP] value). The lesions occur primarily in the distal femoral, distal tibial, and proximal tibial regions, although vertebral lesions are seen in approximately one fourth of cases.[192] Patients may have 1 to 18 lesions at a time; biopsy specimens show a nonspecific chronic inflammatory process, and no organisms are identified histologically or by culture. Approximately 20 percent of patients have a pustular eruption of the palms and soles *(pustulosis palmaris et plantaris)* at the same time that they come to medical attention with bone lesions.

CRMO is a sporadic illness in most cases, but it may also be found as part of syndromic illnesses. Majeed syndrome, for example, is an autosomal recessive, lifelong disorder composed of CRMO, congenital dyserythropoietic anemia, and transient inflammatory dermatosis.[71] It may also occur in the rare patients with deficiency of interleukin-1 receptor antagonist.[3]

The long-term outlook for children with sporadic CRMO disease generally is good, although numerous relapses may occur.[19] Glucocorticoids and nonsteroidal anti-inflammatory drugs are used therapeutically, although recurrences are common. Treatment with interferon-γ and tumor necrosis factor–α blocking agents, bisphosphonates, and other agents has been reported to be helpful.[3,58,83]

Diagnosis

The diagnosis of osteomyelitis generally is suspected based on the presence of fever, focal skeletal pain, warmth, swelling, and a limp or refusal to use an extremity. The diagnosis is confirmed by identification of organisms by culture or Gram stain in an aspirate of bone or by histopathologic evidence of inflammation in surgical specimens of bone. In an otherwise healthy individual, the diagnosis is probable when a patient has fever, leukocytosis, elevated acute-phase reactants (elevated CRP or ESR), or a positive blood culture plus one or more of the following: abnormal results of imaging studies (plain radiograph, magnetic resonance imaging [MRI], or computed tomography [CT]), scintigraphy, or physical findings consistent with osteomyelitis.

Microbiology

The cornerstone of the diagnosis of osteomyelitis is isolation of bacteria or other microbes from bone or from anatomic structures contiguous to bone. Overall, such cultures (aspirates or surgical specimens from bone débridement, subperiosteal exudate, or joint fluid) provide a bacteriologic diagnosis in 66 to 76 percent of cases. Blood cultures yield an organism in about half of cases (36% to 74% of patients in several series).[165,219,223,227] Recovery of *Kingella* is enhanced by placing aspirates of fluid into blood culture bottles.[239]

In neonates, needle aspiration of soft tissue or incision and drainage of bone may yield the offending organism. In infants and young children, subperiosteal needle aspiration can be done if the point tenderness is localized. In older children and adolescents, noninvasive culturing of the bone is less rewarding. In this age group, windowing or drilling to drain pus from the bone yields valuable material for culture but is controversial; some orthopedic surgeons consider the risk of causing epiphyseal damage and subsequent length discrepancy secondary to the procedure too great. Consequently, blood cultures and imaging methods often represent the extent of the diagnostic evaluation. Nonetheless, it is important to attempt to obtain bacterial cultures early in the evaluation of

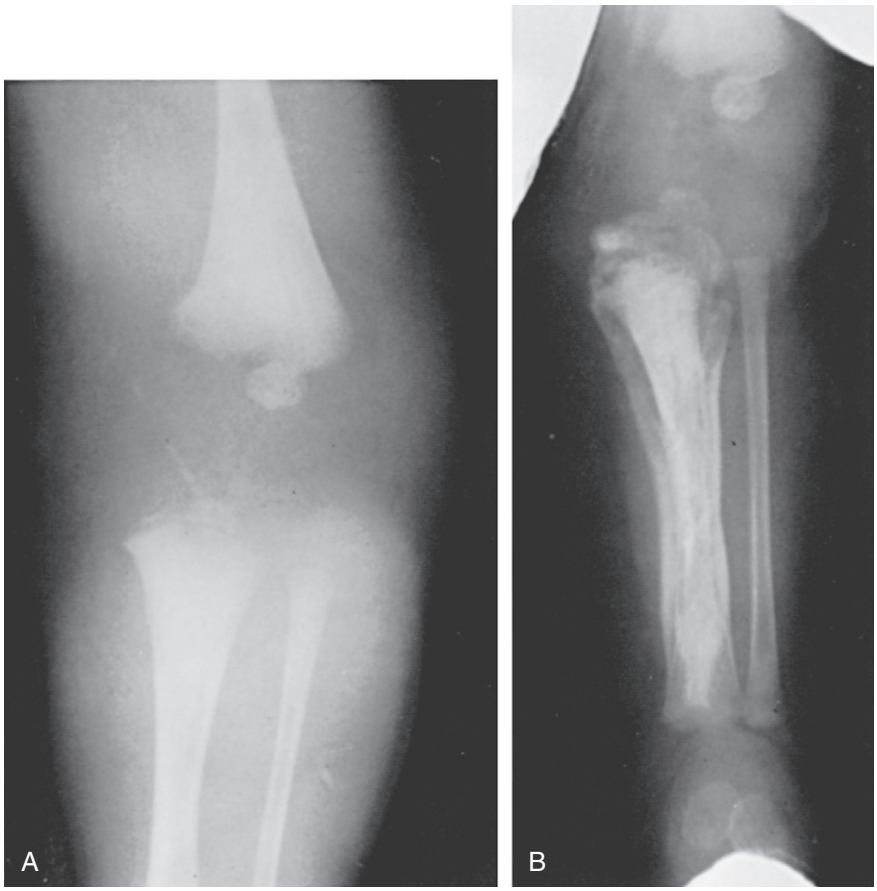

FIGURE 55-3 ■ **A,** The left knee of an infant shows diffuse soft tissue swelling around the proximal ends of the tibia and fibula. **B,** Six weeks later, the subcutaneous fat lines between the muscles and the skin can be seen, as can an involucrum involving almost all of the tibia.

suspected osteomyelitis because decisions about the type and duration of antimicrobial therapy are greatly facilitated by knowing the susceptibility profile of the etiologic agent.

Radiology

Plain Radiographs. Conventional radiographs are crucial in establishing the diagnosis of pediatric osteomyelitis and always should be obtained.[29,44,104] Because bone density must decrease 50 percent to be detected by radiographs,[11] changes in the less ossified bones of neonates are detected more readily than are changes in older children. In contrast, Waldvogel and Papageorgiou[228] found in adults that plain radiographs were of no diagnostic value in 23 percent and were misleading in an additional 16 percent.

Radiographic changes occur in three stages.[37] The first stage, which occurs approximately 3 days after the onset of symptoms, is the formation of a small area of localized, deep soft tissue swelling, usually in the region of the metaphysis (Fig. 55-3). Consequently, when diagnosis of osteomyelitis is sought soon after onset of symptoms, examination of the radiograph should be directed to the soft tissue rather than the bone. During the second stage, which occurs 3 to 7 days after the onset of symptoms, swelling of the muscles with obliteration of the interposed translucent fat planes can be noted. It is caused by continued spread of edema fluid and can progress, particularly in neonates and young infants, to superficial soft tissue edema; the skin may acquire an orange-peel texture.

Radiographic evidence of bone destruction usually is not detected until 10 to 21 days after the onset of symptoms. The first changes detected include subperiosteal bone resorption, areas of bone destruction, and periosteal new bone formation. The variability depends on the specific bone involved; generally, long tubular bones tend to show bony changes 2 to 3 weeks earlier than membranous or irregular bones.

Magnetic Resonance Imaging. MRI has become the imaging modality of choice when additional imaging is needed beyond plain radiographs and has sensitivity in excess of 90%.* The major advantages of MRI are that it accurately delineates subperiosteal or soft tissue collections of pus that might require surgical drainage without using ionizing radiation, and it can identify sinus tracts for removal (Fig. 55-4).[29,76,177,209] MRI often provides more specific anatomic information than CT or plain radiography.

In acute osteomyelitis, bone marrow edema caused by the accumulation of purulent material leads to decreased signal on T1-weighted images. On T2-weighted images of the same area, increased signal is seen. With commonly used sequences, the sensitivity of MRI for the

*References 24, 29, 44, 73, 147, 151.

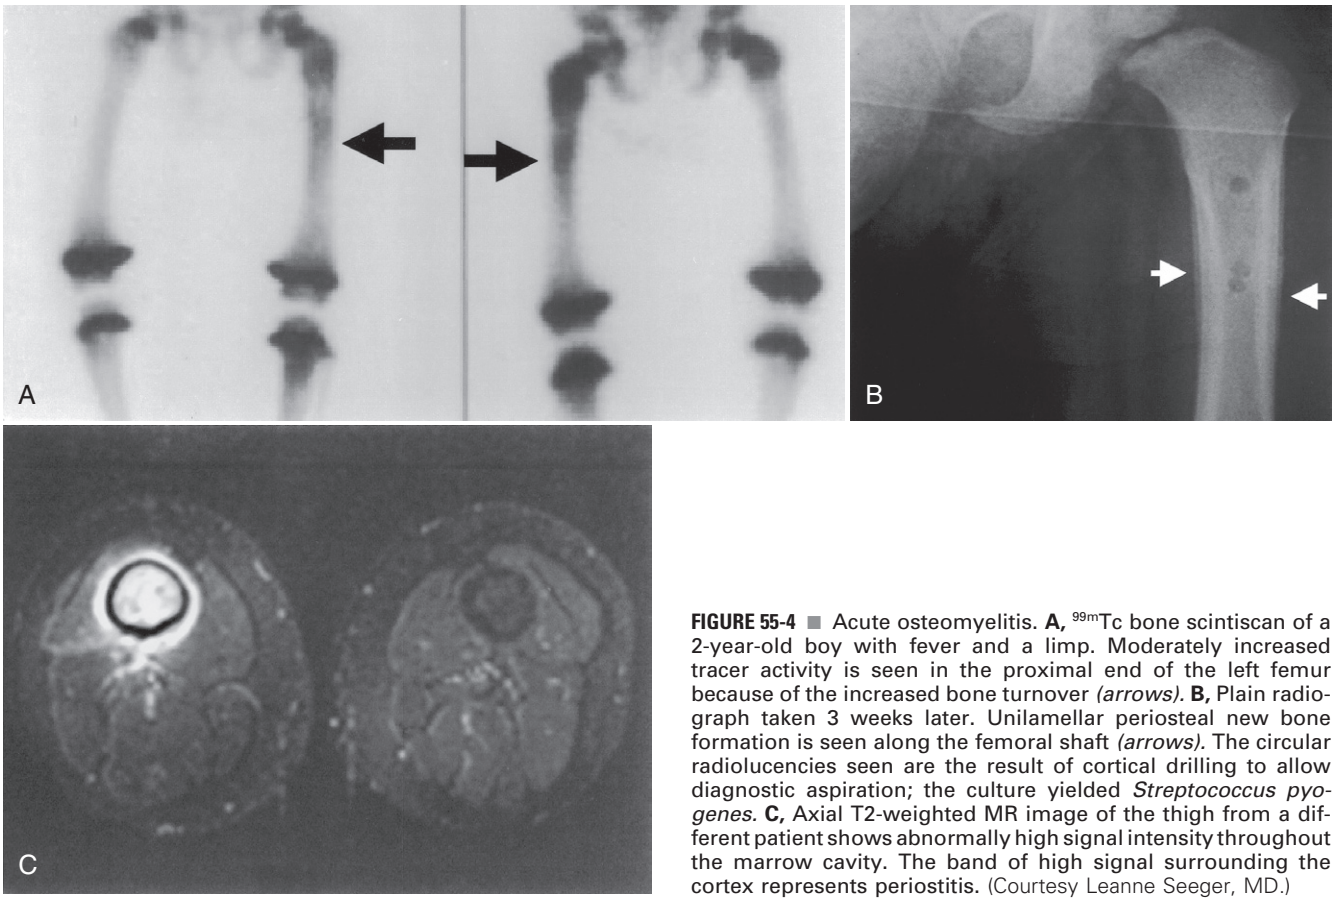

FIGURE 55-4 ■ Acute osteomyelitis. **A,** ^{99m}Tc bone scintiscan of a 2-year-old boy with fever and a limp. Moderately increased tracer activity is seen in the proximal end of the left femur because of the increased bone turnover *(arrows).* **B,** Plain radiograph taken 3 weeks later. Unilamellar periosteal new bone formation is seen along the femoral shaft *(arrows).* The circular radiolucencies seen are the result of cortical drilling to allow diagnostic aspiration; the culture yielded *Streptococcus pyogenes.* **C,** Axial T2-weighted MR image of the thigh from a different patient shows abnormally high signal intensity throughout the marrow cavity. The band of high signal surrounding the cortex represents periostitis. (Courtesy Leanne Seeger, MD.)

detection of acute osteomyelitis may approach 100 percent.[151] Fat-suppression sequences, including short-tau inversion recovery, decrease the signal from fat. Inversion recovery sequences allow more sensitive detection of bone marrow edema. MRI may have a particular advantage in establishing the diagnosis of spinal osteomyelitis because a clear distinction can be made between the vertebral body and the adjacent disk. Loss of this border is one of the first abnormalities detected by MRI in spinal osteomyelitis.

The need for sedation in most infants and children and the cost of MRI are the major disadvantages that continue to limit its use. In addition, infarction and other processes can alter the appearance of bone marrow and lower the specificity of MRI and must be considered in the interpretation of the imaging study.

Radionuclide Imaging. Radionuclide scanning has been used for decades in the evaluation of suspected osteomyelitis. Despite the fact that bone scintigraphy involves exposure to ionizing radiation, it continues to be used widely because of its ready availability and utility in detecting multifocal disease.[64] Bone imaging employing technetium-99m (^{99m}Tc) diphosphonate scintigraphy is used most frequently. After being injected, the phosphate adduct is adsorbed to the surface of the hydroxyapatite crystal in bone, and the isotope becomes concentrated in the cement line located at the junction of osteoid and mineralized bone.[216]

In most institutions a three-phase bone scintiscan is performed for evaluation of infection. Shortly after injection (2 to 5 seconds), a nuclear angiogram (flow phase) of the area of suspected osteomyelitis is obtained. The second (blood pool) phase consists of a single image obtained 5 to 10 minutes after injection. The third image is obtained 2 to 4 hours after injection. In this last phase, specificity of the diphosphonate compounds for the bone is revealed. Anything increasing local blood flow to the area, particularly if accompanied by inflammation, results in increased general uptake in the first two phases, but osteomyelitis results in focal uptake in the third phase, with the intensity of the signal detected reflecting the level of osteoblastic activity.*

Acute osteomyelitis in children is often diagnosed by a ^{99m}Tc scan and treated successfully before bone changes are detected by plain radiographs (see Fig. 55-4).[218] With sensitivity previously reported to be as high as 95 percent, bone scintiscanning has until recently been a reliable tool in establishing the diagnosis of osteomyelitis.[37] Unfortunately, in one recent report, bone scintigraphy detected only osteomyelitis caused by CA-MRSA cases in 53 percent (26/49) of children.[29] This apparent lack of sensitivity for CA-MRSA may reflect the acuity of disease caused by this pathogen, because changes in radionuclide scans are more characteristic when patients have had an illness of longer duration.[195]

*References 40, 55, 57, 64, 88, 128, 193.

In addition, bone scintiscans that use ^{99m}Tc may be nondiagnostic in neonates.[9,79] The false-negative result of bone scintiscans probably is due to the paucity of mineralization in neonates' bones. Ischemia of bone, probably caused by infarction, also has been noted on the initial bone scintiscan.[158] The sensitivity of bone scintigraphy in neonates varies in different studies of neonates and ranges from as little as 31 to as high as 90 percent.*

Older infants with osteomyelitis and a nondiagnostic ^{99m}Tc bone scintiscan also have been described.[26,103] In such instances, a gallium-67 (^{67}Ga) scan may be valuable. ^{67}Ga is a transition metal that, similar to iron, is bound to plasma proteins; the unbound portion (10% to 25%) is excreted in urine. It localizes in inflammatory foci because of increased capillary permeability (leaking plasma proteins), in vivo leukocyte labeling, binding to lactoferrin in the lesion, and perhaps direct bacterial uptake. Because of the slower elimination of gallium from blood, its uptake in an inflammatory focus depends less on blood flow. Delayed elimination often results in poor contrast of bone to soft tissue, however, and delays making a reliable interpretation for 24 to 72 hours after injection.[109] In one study, 15 of 16 cases of osteomyelitis with a nondiagnostic ^{99m}Tc scan had changes on ^{67}Ga scan typical of osteomyelitis.[201] Combined evaluation with ^{67}Ga imaging and ^{99m}Tc bone scintigraphy may lead to greater diagnostic certainty when the studies are not conclusively diagnostic.[198,238] Despite these successes, ^{67}Ga scans are seldom employed because repeating MRI or plain radiographs and clinical improvement during therapy usually are sufficient to resolve initial diagnostic uncertainties.

Numerous studies have been conducted to examine the utility of indium 111–labeled leukocyte scans for the diagnosis of osteomyelitis. This method involves removing leukocytes and injecting them back into the patient after in vitro labeling. It has a reported sensitivity of 86 percent,[190] which seems to be best for the detection of lesions in long bones. False-positive scans can result from a variety of processes, including fracture and infarction. Enthusiasm for this modality also is limited by the higher organ absorption of the radiation dose.[81] Numerous other scintigraphic methods for the detection of osteomyelitis, including ^{99m}Tc-hexamethylpropyleneamine oxime–labeled leukocytes and monoclonal antibodies, have been examined. At present, these alternative methods do not offer any advantage over MRI and older radionuclide imaging approaches.

Computed Tomography. CT is used occasionally in the diagnosis and management of osteomyelitis because it provides excellent definition of cortical bone and high spatial resolution. CT abnormalities commonly found in osteomyelitis include increased density of bone marrow caused by the accumulation of purulent material and periosteal new bone formation and purulence. CT is particularly useful in detecting sequestra and delineating subperiosteal abscesses. It previously has been used to define infections of the spine, but MRI has largely replaced CT for this indication.[73,118]

*References 9, 56, 66, 79, 126, 158, 232.

Treatment of Acute Hematogenous Osteomyelitis

The need for surgical therapy must be considered immediately when osteomyelitis is diagnosed. Reports of soft tissue, subperiosteal, and intramedullary abscesses have become common in the early 21st century, mirroring the increased prevalence of skin, soft tissue, and musculoskeletal infections caused by CA-MRSA.[8,120,148] MRI, ultrasonography, and CT may prove useful in assessing these purulent foci.[29] Drainage of these sites by surgical or interventional radiology techniques also provides the opportunity to obtain cultures to confirm a microbiologic diagnosis. Sequestra should be removed if present. If contiguous infectious foci are present, they should be débrided adequately and treated with effective antimicrobial therapy. Immobilization of the affected extremity or splinting may afford relief from pain and sometimes is used to prevent the development of pathologic fractures when extensive bone involvement is detected by plain radiography.

The initial therapy should have potent activity against *S. aureus* and group A streptococci because these pathogens represent the primary causes of osteomyelitis. Acute bacterial hematogenous osteomyelitis should be treated initially with parenteral anti-infective agents, in view of the high mortality rate in *S. aureus* osteomyelitis seen in the preantibiotic era and more recent reports of fulminant disease with CA-MRSA.[94,95,99,111,148]

The choice of initial therapy has become more complex with the marked increase in prevalence of CA-MRSA in the United States and other countries. In areas where most (≥90%) *S. aureus* isolates remain methicillin susceptible, initial therapy may consist of a penicillinase-resistant, semisynthetic penicillin, such as nafcillin or oxacillin, administered parenterally in a dosage of 150 to 200 mg/kg/day in four divided doses.[98,114,184] Cefazolin, a first-generation cephalosporin, and cefuroxime, a second-generation cephalosporin, have also been used for empirical therapy, with good results, and may be preferred in infants and children younger than 36 months of age if *Kingella kingae* is strongly suspected based on clinical features.[165,240] In areas where CA-MRSA is common, either vancomycin or clindamycin (if >90% of CA-MRSA isolates are susceptible) should be included in the initial empirical therapy for CA-MRSA.[120,149] Currently, most isolates of CA-MRSA remain susceptible to clindamycin, but clinical laboratories should screen for inducible macrolide-lincosamide-streptogramin resistance using the D-test or similar methodology.[8,120,136]

Although protein conjugate vaccines have all but eliminated *H. influenzae* type B infections in the United States, antimicrobial coverage for this possibility should be considered for younger children who have not yet completed their immunization series. In these circumstances, addition of a third-generation cephalosporin (ceftriaxone or cefotaxime) to the empirical antistaphylococcal agent (vancomycin, clindamycin, oxacillin, or nafcillin) might be warranted. Other agents may be administered when epidemiologic factors suggest the possible presence of other pathogens: third- or fourth-generation cephalosporins for *P. aeruginosa*, *Salmonella*

species, or other enteric gram-negative organisms and clindamycin for suspected anaerobic infections.[70,183]

When an organism is isolated or identified by other means, antimicrobial therapy can be chosen with greater specificity. Staphylococci should be treated with penicillin G if the organisms are susceptible to this antibiotic. In most cases, staphylococci must be treated with a penicillinase-resistant penicillin (oxacillin or nafcillin), clindamycin, or vancomycin. Ceftriaxone also has proved successful in the treatment of most cases of MSSA. Oxazolidinone (linezolid) and streptogramin (quinupristin-dalfopristin) drugs have been used successfully for the treatment of osteomyelitis with MRSA and MSSA[61] and for the treatment of vancomycin-resistant enterococci, but this experience is limited.[41]

Trimethoprim-sulfamethoxazole (cotrimoxazole) and the lipophilic tetracyclines (minocycline and doxycycline) are readily absorbed by the oral route and have been used successfully in the treatment of osteomyelitis in both children and adults. One study reported consistent success in 20 children treated with cotrimoxazole, including several children with CA-MRSA infections.[154] However, experience remains limited with using cotrimoxazole or tetracyclines, especially for treatment of CA-MRSA infections in which pneumonia and bacteremia are common, and the potential for dental staining with tetracyclines must be kept in mind. Daptomycin, a bactericidal lipopeptide antimicrobial agent, has excellent activity against CA-MRSA, but pediatric pharmacokinetic data and clinical experience also are limited. Moreover, daptomycin has poor activity in lung tissue, adding to concerns about the utility of daptomycin for the treatment of CA-MRSA osteomyelitis.[41,94,95,120]

Osteomyelitis caused by *S. pneumoniae* strains with decreased susceptibility to penicillin have been managed successfully with a variety of agents, including ceftriaxone, vancomycin, and clindamycin.[26] β-Lactam antibiotics, including oxacillin, nafcillin, and cephalosporins, have been used successfully in the treatment of *K. kingae* infection, although cefazolin may be preferable to antistaphylococcal penicillins, because the latter have relatively lower activity.[40,96,239-241]

Decades of experience and clinical investigation have led to wide acceptance of sequential use of the intravenous and oral routes of administration of antibiotics to treat pediatric osteomyelitis, which previously was controversial. Completing treatment with oral therapy avoids the cost, pain, inconvenience, and well-known complications of long-term intravenous administration of antibiotics. The relative safety of central venous catheters has not obviated these concerns. To the contrary, local skin infections, bacteremia, and malfunctions of the catheters are common occurrences when used for osteomyelitis treatment, especially in young children.[188,244]

Oral therapy is most likely to succeed, and oral therapy is an acceptable option when the following criteria are met: an organism has been identified, the patient has the ability to swallow and retain an appropriate medication, the laboratory is able to monitor the degree of antibiotic absorption, and the patient has a clear clinical response to intravenously administered antibiotics.[165,167] In most series in which oral therapy has been evaluated,[32,59,165,215,229] treatment was continued with intravenous antibiotics until the patient was afebrile, until local signs and symptoms of infection were reduced considerably, and until the patient was maintaining caloric and fluid balances by the oral route. In severe or complicated cases, an advisable approach is to delay switching to the oral route until the peripheral leukocyte count has normalized, and the ESR has decreased by 20 percent or more, or until a marked decrease in the concentration of CRP has occurred.[184,223] A review of case series employing sequential therapy affirmed these recommendations and found no evidence that a fixed period of intravenous therapy is beneficial or essential.[132] A transition to oral therapy within 7 days of diagnosis seemed to be equal in outcome to therapy with a fixed initial period of parenteral therapy.

When oral therapy is begun, most antibiotics administered orally for osteomyelitis must be given in doses higher than the doses used for the treatment of other infections.[11,166,215] Specific antibiotics and the recommended starting doses are listed in Table 55-3. Dosages of β-lactams often can be increased to 200 mg/kg/day without having serious adverse side effects. Diarrhea, an infrequent complication of high-dose, oral β-lactam therapy, can be mitigated by a reduction in dose and the administration of probenecid 40 mg/kg/day every 6 hours, with a maximal dose of 2 g/day.[32,165,215] Clindamycin readily achieves high bone levels and does not require higher dose therapy when given orally.[121,149]

The assumption implicit in successful oral therapy is that the antibiotic reaches an effective concentration at the focus of infection. Compliance with the prescribed dose and frequency and absorption into the bloodstream are necessary to fulfill this assumption. Patient (or parent) education and a continuing time commitment by a physician or nurse are essential to maintaining the compliance required for successful treatment. Although eschewed by some physicians,[146,171] therapeutic drug monitoring (TDM) is recommended by some specialists to show that adequate absorption of orally administered antibiotics is occurring.[166] This recommendation stems from the observation that rare patients have inadequate serum levels despite receiving high oral dosages. TDM also can be used to document adherence to the therapeutic regimen.[215]

TDM was initially performed by measuring serum bactericidal activity, targeting a peak serum bactericidal

TABLE 55-3 **Initial Antibiotic Doses for Oral Treatment of Osteomyelitis**

Drug	Dose (mg/kg/day)	Interval between Doses (hr)
Amoxicillin	100	6
Cephalexin	150	6
Chloramphenicol	75	8
Clindamycin	40	8
Cloxacillin	125	6
Dicloxacillin	100	6
Penicillin V	125	4

Data from references 32, 84, 165, and 215.

titer of 1:8 or greater.[178,215] However, this assay is confounded by other antibiotics present in the serum sample; for example, nafcillin administered intravenously would interfere with evaluating the oral bioavailability of oral dicloxacillin. Chemical assays of a specific agent circumvent this problem. Dicloxacillin can be administered orally and the dose adjusted based on dicloxacillin measurements before the intravenous administration of another β-lactam has been discontinued. This procedure avoids several days of inadequate therapy should the dosage of the oral agent need to be adjusted.

In most cases, clinical improvement is evident within 3 to 7 days of the initiation of appropriate therapy. To help show that effective therapy is underway, it is helpful to monitor acute-phase reactants. Although CRP and ESR usually increase during the first 3 days of therapy, CRP then begins to decrease rapidly and typically returns to normal in 7 to 10 days. CRP returns to normal levels in blood more rapidly in children with an uneventful clinical course than in children who ultimately require repeated surgical drainage.[184] A slow decline in serum CRP to normal levels has been associated with more extensive radiographic changes or persistent symptoms 1 to 2 months after discharge from the hospital. Similar to CRP, ESR generally increases during the first several days but declines in the weeks that follow.[223] Failure of ESR to decrease during the second week of treatment may indicate a need for surgical drainage or the development of chronic osteomyelitis.[208]

Prolonged antibiotic therapy is essential for successful treatment of acute osteomyelitis. In one early report of 45 cases of osteomyelitis, four treatment failures occurred; all of the patients had been treated for 10 days or less.[105] Likewise, Dich and colleagues[59] noted a 19 percent failure rate in 37 patients treated for 3 weeks or less; the rate was 2 percent in 48 patients treated for 21 to 50 days. Blockey and Watson[22] provided similar data. Thus, 3 weeks or more appears to be the minimal duration of therapy for hematogenous osteomyelitis to minimize the risk of recurrence. A conservative but individualized approach is to administer antibiotics until the ESR and CRP are within the normal range, which usually requires 4 to 6 weeks of treatment.[120,165–167,208]

Special Manifestations of Hematogenous Osteomyelitis

Brodie Abscess

Osteomyelitis occasionally is indolent in presentation. Perhaps the best defined example is subacute osteomyelitis with the development of an intraosseous abscess (Brodie abscess).[204] These patients most often are adolescents with complaints of long bone pain and tenderness. The ESR usually is normal at the time of presentation. A bony defect with sclerotic margins is detected by plain radiography in most patients. A distinctive "target" lesion has been described after MRI of Brodie abscesses.[147] Concentric layers are seen and reflect a central abscess cavity surrounded by an inner ring of granulation tissue, an outer ring of fibrotic reaction, and a peripheral rim of endosteal reaction that is hypointense on T1-weighted images.

Treatment consists of surgical drainage and curettage followed by antimicrobial therapy, as for other forms of hematogenous osteomyelitis. A variety of organisms, including *H. influenzae*, have been isolated from these lesions,[129] but *S. aureus* and other gram-positive cocci are the pathogens usually involved. The prognosis generally is good, although deformities occur in some cases.

Osteomyelitis in Patients After Closed Fractures

Acute hematogenous osteomyelitis sometimes develops after closed fractures of tubular bones occur.[36,230] A clue to diagnosis is the resumption of pain after the initial postfracture pain has subsided, usually 1 to 6 weeks after the injury occurs. The pain differs from that associated with the fracture by being progressive, and it is not relieved by immobilization. Patients are febrile and may be thought to have another focus of infection before osteomyelitis is discovered. When the cast is removed, local erythema, fluctuance, and warmth are apparent and out of proportion to the normal healing of fracture. Although usually caused by *S. aureus*, anaerobic superinfection of staphylococcal osteomyelitis at the fracture site has been described.[213] Successful therapy requires adequate débridement, administration of appropriate antibiotics, and external fixation in some cases.

Epiphyseal Osteomyelitis

Rarely, hematogenous osteomyelitis may arise in the epiphyses of the tubular bones of young children.[1,86,142,220] Although the pathogenesis is unclear, it may involve delivery of microorganisms to the epiphyses by transphyseal vessels. After the child reaches 15 to 18 months of age, these vessels are lost, and the physis acts as a physical barrier to the spread of infection from the metaphysis. The vascular anatomy of the epiphysis is very similar to that of the metaphysis, however, and in some cases infection may occur when bacteria are delivered to venous sinusoids by terminal branches of the epiphyseal arteries.

Hematogenous epiphyseal osteomyelitis may be acute or subacute. In the acute manifestation, septic arthritis initially may be diagnosed when joint swelling occurs and abnormal fluids are removed by diagnostic aspiration. In cases with a more indolent course, pain, limp, or other symptoms prompt an evaluation for the possibility of an osteoarticular infection. The correct diagnosis typically is established when a radionuclide bone scintiscan or plain radiographs taken weeks later show evidence of increased bone turnover or the lytic changes characteristic of osteomyelitis. Administration of appropriate therapy for epiphyseal osteomyelitis has been followed by complete recovery without apparent sequelae 2 to 6 years after diagnosis.

Involvement of Nontubular Bones

Less than 20 percent of all cases of osteomyelitis involve nontubular bones. Infection of the calcaneus seems to be

the most common (see Table 55-2).[165] In patients with hematogenous infection, destruction occurs just under the epiphyseal line in the metaphysis posteriorly and medially, where the blood supply is greatest. It is present in all patients, in addition to destruction of the adjacent epiphysis, particularly in its middle to superior portion. Periosteal new bone formation occurs very late, with 3 to 4 months required for reossification. Osteomyelitis in the other cuboidal bones rarely occurs.

Almost equal in frequency to infection of the calcaneus is infection of the bones of the pelvis.[165] Of the bones of the pelvis, the ischium is involved most commonly. The next most frequently involved bone is the ilium, followed by the sacroiliac joint. The pubis is involved in only 20 percent of cases of pelvic osteomyelitis.[107,163] Pelvic osteomyelitis causes an increase in the ESR in nearly all patients, and two thirds have a peripheral leukocyte count greater than 10,000 cells/mm^3.[163] The most common organism causing pelvic osteomyelitis is *S. aureus*, which is isolated from either blood or an aspirate from the bone lesions in approximately 80 percent of cases.

Establishing the diagnosis of pelvic osteomyelitis often is difficult. Most patients are judged to have disease in the hip at the time that medical attention is sought. Most often, patients with pelvic osteomyelitis have hip pain and a gait abnormality but allow their hips to be put through a passive range of motion. Point tenderness at the site of the lesion can be elicited in approximately 50 percent of these patients. Sacroiliitis frequently is difficult to identify by clinical examination. Pressing down on the pelvis, which stresses the sacroiliac joint, produces local pain. Tenderness in the buttocks or the sciatic notch, if present, is an invaluable diagnostic finding.[2,43,63,159,233] Pelvic osteomyelitis can mimic appendicitis and urinary tract infection[233]; it occurs more frequently in individuals with inflammatory bowel disease. In most patients, plain films of the pelvis are not rewarding, whereas ^{99m}Tc bone scintiscans indicate the diagnosis in approximately 90 percent of cases.[144,163] CT may reveal infection not evident by bone scintigraphy. MRI also is likely to identify pelvic osteomyelitis.[222] Antibiotic therapy alone is adequate in most cases of pelvic osteomyelitis. Surgery is indicated only when a lack of response to antimicrobial therapy occurs. Osteomyelitis in the pelvic bones has a good prognosis; chronic infection and sequelae are rare events.

Hematogenous osteomyelitis of flat bones occurs rarely and has been described in the skull, ribs, sternum, and scapula.[91,160,165,224]

Spinal Osteomyelitis

Spinal osteomyelitis can involve either the intervertebral disk or the vertebral bodies per se. Conceptualizing these infections as different entities is worthwhile because of the different pathophysiology and prognosis.[73]

Diskitis. The intervertebral disk consists of three components: the paired cartilaginous articulation, the fibrous ring (anulus fibrosus), and the nucleus pulposus.[25,73] The axial vessels that parallel the fetal notochord are atrophied by birth, with the avascular, mucilaginous nucleus pulposus remaining. The disk has two arterial supplies: periosteal vessels and vessels descending from the central portion of the vertebral body.[48,72] The vessel from the central portion of the adjacent vertebra begins to atrophy in the first year and is obliterated completely by the time the child is 10 years old. This condition leaves only the capillary network in the anulus fibrosus, which is derived from the terminal radial ramifications of the periosteal vessels. If loss of this vascular supply is precipitous, idiopathic disk necrosis ensues, usually manifested as asymptomatic calcification.[191,206,212] If bacteremia occurs during loss of the blood supply, however, infection of an intervertebral disk may occur.

Infection of an intervertebral disk has no sex preponderance, and most children are younger than 5 years old.[73,197] It occurs almost exclusively in the lumbar region (the L4 and L5 disks are involved most frequently, followed by L3 and L4). The disease comes to medical attention with the patient's refusal to walk. Backache and a progressive limp may be present. Nonambulatory infants often become irritable and refuse to sit. On examination, the most striking feature is percussion tenderness over the contiguous spine; hip pain and stiffness with loss of lordosis of the lower part of the back are observed. Occasionally, compression of the spine produces pain at the infected disk. The mean duration of symptoms before diagnosis is established ranges from 1 day to 18 months. Most patients have had symptoms for several weeks.

Lesions in higher locations (T8 to L1) can mimic gastrointestinal disease with abdominal pain, ileus, and vomiting, but the most important entities in the differential diagnosis are vertebral osteomyelitis and spinal or paraspinal tumors. Most patients have a history of a recent upper respiratory tract infection.[124,131,182,187,200] Fever generally is absent or of low grade. Peripheral leukocytosis is present in one third of patients, and virtually all have an increased ESR. A few patients undergoing biopsy have cultures that grow microorganisms. Most commonly, *S. aureus* is recovered, along with rare isolates of pneumococci and gram-negative organisms, including *K. kingae*. Evaluation for suspected diskitis usually involves careful elicitation of the history and physical examination, a complete blood cell count, determination of the ESR, a blood culture, and plain lateral radiographs of the lumbosacral spine.[73]

Typical plain radiographic findings are shown in Figure 55-5. The first finding is narrowing of the disk space, which usually is not detectable until 2 to 4 weeks after the onset of symptoms. Frequently, this narrowing is overlooked if loss of the normal progressive (from cephalad to caudad) increase in disk width is not appreciated. It is followed by destruction of the adjacent cartilaginous vertebral end plates and, subsequently, by herniation of the disk into the vertebral body. Rarely, compression or wedging of the vertebral body is noted. In older children, anterior spontaneous fusion is a common finding. In all individuals, reactive bone proliferation is a rare finding, as are paravertebral soft tissue masses.

Because of overlap of this syndrome with noninfectious disk necrosis, investigators in the earlier literature advocated treating this disease solely by bed rest. In view of the low yield and generally favorable prognosis of

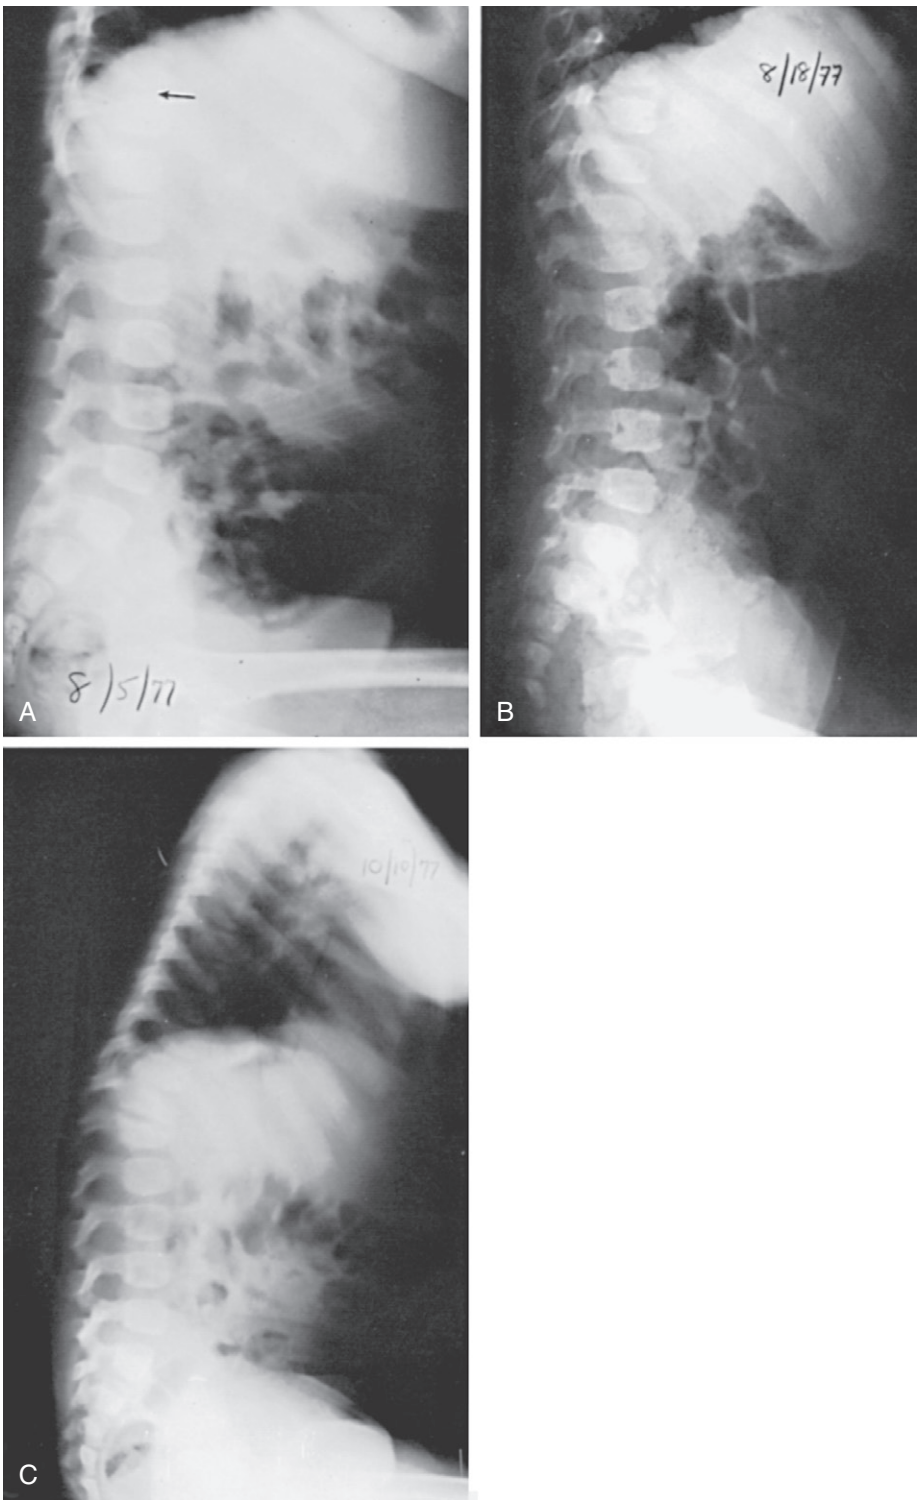

FIGURE 55-5 ■ Diskitis. **A,** Lateral lumbosacral spine of a 13-month-old child who had low-grade fever and refused to walk. The *arrow* indicates the narrow disk space. **B,** Follow-up examination 2 weeks later shows almost complete collapse of the intervertebral body. **C,** Two months later, destruction of the contiguous vertebra with marked kyphosis was apparent. (Courtesy Joel Blumhagen, MD.)

diskitis, biopsy or aspiration for culture generally is unnecessary. Although controversial, oral antistaphylococcal therapy often is administered for a prolonged period (5 to 6 months).[73] Other physicians have suggested giving 5 to 7 days of intravenous antistaphylococcal therapy, followed by 7 to 14 days of a similar oral agent.[50] Very young children generally do well, and the disk space is preserved; spontaneous spinal fusion occurs commonly in older individuals.

Vertebral Osteomyelitis. The intervertebral disk loses its vascular supply with age, a process usually completed

by 30 years of age. As a result, bacteremic pyogenic infections of the spine occur most often in the vertebral bodies. The venous drainage of the vertebral bodies is composed of three different freely communicating, but valveless, systems. Intraosseous vertebral veins drain the center of each body and form a large channel that exits through the nutrient foramen. They anastomose with the anterior and posterior internal plexus (between the dura mater and the vertebral body). The internal venous plexus has anastomotic connections with the external venous plexus through the vertebral ligaments. The external venous plexus communicates freely with the segmental veins on the ventral surface of the body wall (Batson plexus).

Reversal of blood flow or thrombosis in the sluggishly flowing vertebral veins is thought to be the first event in the development of vertebral osteomyelitis. Because of the vascular communication, osteomyelitis usually involves two adjacent vertebral bodies, with the interposed disk initially skipped. The same process of septic thrombophlebitis involving the internal venous plexus can produce an epidural abscess (with cord compression) and infarction of the vertebral body. Spread along the external venous plexus can lead to a paraspinous mass. In the thoracic area, it may produce mediastinitis[54]; and in the cervical area, a retropharyngeal abscess can occur. The lumbar area is involved much more frequently than is the thoracic area, which is involved more frequently than is the cervical region.[5,118,205]

Children with vertebral osteomyelitis usually are older than 8 years of age and seek medical attention because of constant back pain. They may appear toxic and have a low-grade fever (>39° C [102.2° F]) after an indolent course (2 weeks to several months).[73] Percussion of the spinal dorsal process frequently elicits exquisite tenderness. Usually, the paraspinous muscles around the involved vertebrae are in spasm, with rigidity of the area. Radiographic examination of a patient with vertebral osteomyelitis shows the earliest change to be localized rarefaction of one vertebral plateau, followed by involvement of adjacent vertebrae. Marked destruction of the bone, usually anteriorly, is followed by abundant anterior osteophytic reactions with bridging and bone sclerosis (Fig. 55-6).

MRI is useful in establishing the diagnosis of vertebral osteomyelitis[157] because the vertebral disk and the vertebral body are clearly discernible. Most cases of vertebral osteomyelitis begin at the margin between the disk and the anterior part of the vertebral body. In some cases, MRI has detected evidence of osteomyelitis when radionuclide imaging studies were normal.[217] Distinguishing pyogenic osteomyelitis from tuberculous lesions radiologically is impossible, but the latter usually are characterized by less bone destruction, less bone proliferation, and less sclerosis. The osteophytic bridging between adjacent vertebrae is extremely rare in spinal tuberculosis.

^{99m}Tc and ^{67}Ga are taken up by the lesion in vertebral osteomyelitis. A possible advantage of scanning with both isotopes is identification of paraspinous abscess with ^{67}Ga,[189] but MRI probably would accomplish the same goal.

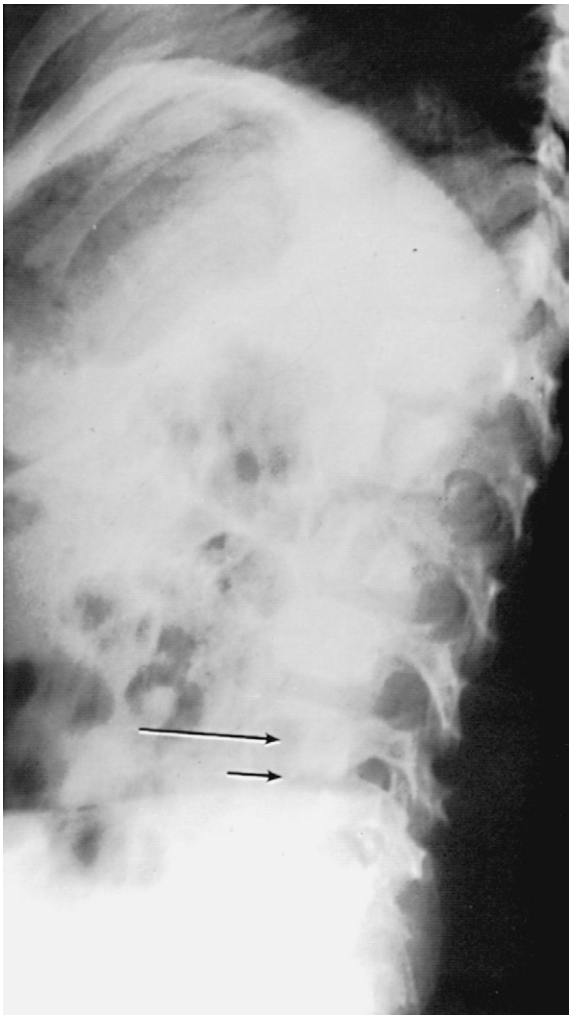

FIGURE 55-6 ■ Vertebral osteomyelitis. The *large arrow* indicates the lytic lesion with some anterior sclerosis in the lumbar vertebra. The *small arrow* indicates involvement of the adjacent lower vertebra and narrowing of the disk space. (Courtesy Joel Blumhagen, MD.)

Most cases of vertebral osteomyelitis are caused by *S. aureus*. Organisms causing urinary tract infection can cause osteomyelitis, presumably by local spread through the Batson plexus.[30,106,134] Urinary tract infection rarely precedes the development of vertebral osteomyelitis, however, and only approximately 2 percent of all cases can be shown to be related to infection of the urinary tract.[85] The best method of establishing the diagnosis is through examination of bone biopsy specimens and cultures.[164] *P. aeruginosa* is sometimes found to cause vertebral osteomyelitis in injectable drug users, and the organisms presumably were inoculated along with the illicit drug. Young heroin addicts have been found to have *P. aeruginosa* infection in their intervertebral disks.[31,194] In areas of the world where brucellosis is endemic, spinal osteomyelitis caused by *Brucella* spp. needs to be considered.[139] *Bartonella henselae* also has been found to cause vertebral osteomyelitis.[73] Fungal pathogens causing vertebral osteomyelitis include *Coccidioides* species in endemic areas and *Candida* spp. (often in immunocompromised patients).[155]

Therapy for vertebral osteomyelitis generally includes immobilization. Whether immobilization should be accomplished by simple bed rest or with a body cast is unclear, but bed rest is often used to provide pain relief. Administration of an antibiotic is always indicated. The average duration of treatment of bacterial vertebral osteomyelitis is 2 months; however, no data are available that can be used for determining the most appropriate duration. The need for surgical drainage in some cases should not be overlooked because spinal cord compression caused by an epidural or subdural abscess can lead to permanent paraplegia. A paraspinal focus of infection may rupture into the abdominal cavity or erode the aorta; both events are catastrophic complications.[80] The optimal therapy for fungal infection of the vertebra is unclear.

Hematogenous Osteomyelitis in Special Populations

Osteomyelitis in Neonates

Infection of the bones of neonates has distinct physiologic and clinical features that warrant emphasis.[10,56,238] Although it is rare, neonatal osteomyelitis may occur in neonates with certain risk factors, such as prematurity, skin infections, and complicated delivery.[80,126] As indicated earlier, the epiphyseal-metaphyseal junction frequently is within the joint capsule, and blood vessels that penetrate the epiphysis are common findings, particularly in the hip, shoulder, and knee of the neonate.

In neonates, osteomyelitis in the long tubular bones frequently (50% to 70% of cases) is accompanied by contiguous septic arthritis. Fever is present in one third to one half of these young patients, and, of these, half have a septic or toxic appearance. Fifty percent have multiple bone involvement. Antecedent infections are present in half of the cases and usually are nosocomial; infections of heel puncture sites, arterial cannulas, lungs, and cut-down sites and cephalhematomas have been described.[10] *S. aureus* is the etiologic agent in more than 90 percent of cases; gram-negative bacilli cause a few cases.[238] Osteomyelitis often is identified when a search is instituted for the source or focus of bacteremia.[238] As noted earlier, plain radiographs often reveal evidence of osteomyelitis at the time of diagnosis, whereas bone scintigraphy may be negative. Bone scintigraphy may be useful, however, in excluding the diagnosis of osteomyelitis; in one study, the negative predictive value was estimated at 82 percent.[238]

Although staphylococci seem to be the most common cause of osteomyelitis in infants, group B streptococci have been found consistently in case series.[66] Infants with group B streptococcal osteomyelitis generally are older (2 to 4 weeks old), have no recognized preceding infection, and have only a single bone involved (often the right tibia or humerus).[10]

Osteomyelitis in the skull, an uncommon disease, can occur in neonates. Frequently, it is associated with a cephalhematoma, with or without loss of skin integrity,[133] but it can be caused by fetal monitoring without a cephalhematoma.[152] Numerous bacteria have been isolated from such lesions; as one might expect, most of these bacteria have been present as vaginal flora. Radiographic changes (i.e., bony erosion) are a late finding, but CT of the skull seems to assist in establishing the diagnosis. Infection of a cephalhematoma should be considered if it is enlarging, if it is inflamed, or if laboratory evidence of infection is present, such as an increased CRP concentration or leukocyte count. In most cases, the lesion is drained and treated with an antibiotic appropriate for the infecting organism.

In older descriptions of neonatal osteomyelitis, sequelae were common findings. In more recent series,[126,236] approximately three fourths of all cases have had good outcomes, even when the hip has been involved. When seen, sequelae include avascular necrosis of the femoral head, bony deformities, and shortening of the involved limb.[174]

Osteomyelitis in Long-Term Hemodialysis Patients

Patients undergoing long-term hemodialysis, with multiple invasions of the vascular compartment, seem to be at greater risk for development of hematogenous osteomyelitis.[135] Their indwelling intravenous cannulas can be colonized with coagulase-negative staphylococci or *S. aureus*, and osteomyelitis may develop. The thoracic spine and ribs are the bones most commonly involved; other tubular and cuboidal bones that have been traumatized also can become infected.

Osteomyelitis in Children with Hemoglobinopathies

After pneumonia, osteomyelitis is the most common serious infection in children with sickle-cell disease.[14] Children at risk are children with hemoglobin SS, hemoglobin S-Thal, or hemoglobin SO-Arab and certain children with hemoglobin SC disease.[101,199] The clinical manifestations of osteomyelitis are similar to those of other children with osteomyelitis, but there is a propensity for simultaneous involvement of multiple sites, a tendency toward recurrence, and a greater frequency in children 18 to 48 months of age.

As noted earlier, the microbiology of osteomyelitis in children with sickle-cell disease is complex and dominated by *Salmonella* spp.[14,34] Although *Salmonella* osteomyelitis occurs in less than 1 percent of normal patients with *Salmonella* bacteremia,[234] the frequency of *Salmonella* osteomyelitis in sickle-cell disease is several hundred times that occurring in the general population, with an incidence estimated at 0.36 percent per annum.[14,60,176] Seventy percent of all lesions or blood cultures in children with hemoglobinopathy and presumptive osteomyelitis yield *Salmonella* microorganisms; 10 percent contain *S. aureus;* and aerobic gram-negative rods, including *Shigella sonnei*,[186] *E. coli*,[100] *Serratia* spp.,[78] and *Arizona hinshawii*,[112] are isolated in 7 percent.

Many factors probably contribute to the greater incidence of osteomyelitis in patients with sickle-cell hemoglobinopathy. Injuries to the intestinal mucosa from local thrombosis during a thrombotic crisis may facilitate the entrance of *Salmonella* and other enteric organisms

into the bloodstream.[34,234] When infection of the bloodstream occurs, the splenic dysfunction in these patients may allow a prolonged period or greater magnitude of bacteremia. Evidence of impaired production of opsonic antibodies also exists. Whether bacteria lodge in infarcted bone or whether a different pathogenesis exists is unclear. Infarction occurs in the capital femoral epiphysis, hands, feet, and vertebrae, whereas osteomyelitis involves the metaphyseal-diaphyseal junction of long tubular bones.[67,176]

Infants with hand and foot syndrome are not distinguished easily from infants with osteomyelitis of the phalanges of the hands or tarsal bones of the feet.[28,47,231] The changes caused by osteomyelitis that are seen on plain radiographs are more severe than the changes expected in uncomplicated sickle-cell disease. The most common radiographic findings are a longitudinal intracortical diaphyseal fissure and overabundant periosteal new bone formation. The cortical fissures are thought to represent a layer of purulent exudate in and between the periosteal new bone and dead bone.[60]

Acute infarction and osteomyelitis cannot always be differentiated by MRI, perhaps because of preexisting abnormalities in bone marrow. MRI may be useful, however, for presurgical evaluation. Radionuclide scans also are used frequently to help differentiate osteomyelitis from bone infarction. In theory, bone infarction should have decreased uptake of ^{99m}Tc in the early "blood pool" phase of the scan; increased uptake would be found only as the lesion healed.[123] In one series with 34 sites of infarction, increased ^{99m}Tc uptake occurred in 10, normal uptake occurred in 9, and decreased uptake surrounded by zones of increased concentration occurred in the remaining 15 sites.[89] Ultrasound imaging also has been used to distinguish osteomyelitis and sickle-cell crisis.[25]

Generally, patients with bony infarcts have had dactylitis as an infant and multiple episodes; their temperature usually is less than 39° C (102.2° F). Children with hemoglobinopathy and osteomyelitis may lack this history and have a modest leukocytosis of immature granulocytes.[114] If fever, leukocytosis, and local symptoms persist despite provision of hydration and other supportive measures, needle aspiration of the area must be considered. Identification of an infectious pathogen is particularly important because of the large number of possible organisms involved.

Osteomyelitis in Patients with Human Immunodeficiency Virus Infection

Although recurrent invasive bacterial infections often complicate human immunodeficiency virus (HIV) infection in children and adults, osteomyelitis is not a particularly common complication.[113,153,203] Many of the existing reports involve patients with recent intravenous drug use, which probably acted as a predisposing factor. *S. aureus* was recovered most commonly, although *E. coli*, *Salmonella enteritidis*, *Cryptococcus neoformans*, *Mycobacterium kansasii*, *Histoplasma capsulatum*, and other organisms have also been reported. One recent report, however, suggests that *S. pneumoniae* osteomyelitis may be more common than *S. aureus* infections among HIV-infected children[180] who have not received protein-conjugate pneumococcal vaccines.

Osteomyelitis in Patients with Chronic Granulomatous Disease

The phagocytes of patients with chronic granulomatous disease fail to kill intracellular organisms, and infections with catalase-positive bacteria or fungi are frequent complications. Although staphylococci are a common cause of cutaneous infection in chronic granulomatous disease, osteomyelitis is caused most often by *Serratia* and *Aspergillus* spp. Osteomyelitis is attributed less often to staphylococci, *Pseudomonas*, *Burkholderia*, *Nocardia*, and other bacterial and fungal species.[237]

NONHEMATOGENOUS OSTEOMYELITIS

Puncture Wound Osteomyelitis

Inoculation osteomyelitis most often involves either the patella or the bones of the foot. Soft tissue infections occur after puncture wounds of the foot approximately 15 percent of the time, and osteomyelitis occurs in 1.5 percent of these injuries.[75] Osteomyelitis of the foot that develops after children sustain puncture wounds should be termed *osteochondritis* because it commonly includes infection of the articular cartilage in the metatarsals. Most patients are aged 9 to 18 years. After the initial pain of the puncture wound subsides (in 24 to 48 hours), the signs of osteochondritis appear after another 48 to 72 hours. Typically, joint tenderness and localized swelling, erythema, and pain over the entrance of the puncture wound are present. Fever is an infrequent finding, and the patient seldom has any other constitutional symptoms. No peripheral leukocytosis is noted, and the ESR is increased minimally.

Although the offending organism most commonly is *P. aeruginosa* (90% of the time), staphylococci, streptococci, *Stenotrophomonas maltophilia*,[12] and *Serratia marcescens*[162] also have been isolated.[27,75,115-117] In one series,[116] 20 percent of the cases involved infection with *P. aeruginosa* and *S. aureus*. The predominance of *Pseudomonas* can be explained partially on the basis of the mechanism of injury. *Pseudomonas* is not found commonly in surveys of the microbial flora of the skin of the feet,[93,156,210] but often it is found by culture of the sponge liner from children's sneakers.[74] In addition, many patients in whom *P. aeruginosa* osteochondritis develops have received prophylactic treatment with oral antibiotics that have activity against gram-positive bacteria. A semisynthetic penicillinase-resistant penicillin and an aminoglycoside or ceftazidime often are used as initial therapy.[115,116]

Surgical débridement of necrotic cartilage is a key element of treatment because foreign material frequently is found embedded in the soft tissue; débridement also provides the opportunity to identify organisms resistant to the initial antibiotic agents. The local signs and symptoms of infection usually resolve 4 to 5 days after adequate débridement is performed, and the patient is able to bear weight on the foot. In contrast, antibiotic therapy

alone after diagnostic aspiration may need to be continued 6 to 8 weeks before weight bearing is possible. Long-term follow-up of *P. aeruginosa* osteochondritis indicates that many patients have asymptomatic radiographic abnormalities.[16] Radiographic abnormalities are found more commonly in patients in whom an adjacent joint was involved initially.[16]

Osteomyelitis also has been described repeatedly after puncture wounds occur from stepping on wooden toothpicks. In these cases, *Eikenella corrodens*, a member of the human oral flora, has been found with other organisms. Surgical débridement to remove toothpick fragments and drain local abscesses is essential.[181]

Osteomyelitis of the patella is a disease of children aged 5 to 15 years old, the time in life during which the patella is vascularized. By adulthood, the vessels are almost completely atrophied. In almost all cases, the diagnosis shows the cause to be by inoculation, such as kneeling on a needle. The most common etiologic agent is *S. aureus;* signs of osteomyelitis appear 1 week after the puncture occurs. No constitutional symptoms occur, but extension of the leg produces pain over the anterior aspect of the patella. The diagnosis is made by isolating the organism from the patella. Radiographic confirmation of the diagnosis often requires 2 to 3 weeks. Because the patella lacks periosteum, no periosteal elevation is present, but rarefaction and sclerosis may be seen on the profile view or on tomograms. Treatment of this disease is similar to that for other forms of osteomyelitis.

Osteomyelitis Caused by Spread of Infection from a Contiguous Focus

In children, osteomyelitis related to an infected contiguous focus is a rare finding. Almost all cases of osteomyelitis from a contiguous source in childhood are nosocomial or are associated with infected burn wounds. The probability of postoperative osteomyelitis developing is a function of the surgeon's experience, the technique, the length of time that the wound was open, and whether prophylactic antibiotics were administered. The interval between the precipitating event and pain and the appearance of persistent sinus drainage or ulceration is 2 to 4 weeks. The peripheral white blood cell count often is normal, as is ESR. More than half of cases are caused by multiple organisms. When small draining sinuses are present, correlation between sinus culture and bone biopsy findings is good. With large open areas, organisms obtained by culture of the wound may not be important etiologically, and obtaining a bone biopsy specimen is necessary for making a definitive bacteriologic diagnosis. Staphylococci and streptococci predominate, although gram-negative organisms from the hospital environment often are seen.

Orthopedic Fixator Devices

Infection involving the wires or pins used for orthopedic stabilization represents a diagnostic and therapeutic challenge. Osteomyelitis is suspected when evidence of inflammation or infection is noted near these materials, but it seldom can be proved.[21] Plain radiographs are essential because they may reveal bone destruction at the site of entry of fixation pins. No controlled studies of treatment are available. Soft tissue débridement and removal of necrotic bone should be done as soon as possible, but fixation devices generally are left in place.[13,173] Prolonged therapy usually is given, guided by the susceptibility pattern of any organisms recovered from local cultures.[173]

UNUSUAL MICROBIAL CAUSES OF OSTEOMYELITIS

Actinomyces

More than half of all actinomycotic infections involve the facial or cervical area. The most common site of actinomycotic bone infection is the jaw, with the mandible being involved more frequently than the maxilla. Local signs and symptoms of fever and discharge from a sinus indicate the presence of the disease. Radiographically, periosteal elevation is followed by lytic changes. Often, several "egg shell" areas of new bone are present.

Forty percent of all actinomycotic infections occur in the vertebral bodies. In this illness, the infection almost always is associated with a focus elsewhere; the condition comes to medical attention because of mild pain, tenderness, and some stiffness. It can be distinguished from tuberculosis radiographically by the diffuse honeycombing of the vertebral bodies and the periosteal reaction; large lytic lesions usually are absent. Although no controlled trials of therapy have been done, long-term (>3 months) penicillin G therapy is indicated at doses of 150,000 U/kg body weight per day (i.e., approximately 100 mg/kg/day). Extensive débridement may be needed and has been linked to successful short-term treatment of mandibular actinomycosis.[15]

Brucella

Although an uncommon cause of osteomyelitis in developed countries, *Brucella* spp. are a well-known cause of skeletal infections, most often following the consumption of unpasteurized milk products.[4] *Brucella* spp. can produce abscesses in the vertebral bodies or long bones, although they are not striking features of the disease. The disease often is subacute in presentation, and anorexia, weight loss, sweating, adenopathy, and hepatosplenomegaly are common initial findings. Multidrug treatment is generally successful, with the addition of streptomycin or gentamicin during the first 2 to 3 weeks of therapy.

Fungi

Osteomyelitis may be caused by numerous endemic and opportunistic fungal agents, including various species of *Coccidioides*, *Cryptococcus*, *Candida*, *Blastomyces*, and *Aspergillus*.[127] *Sporothrix* infections occur but are rare.[243] Coccidioidomycosis often follows an earlier acute illness with cough, chest pain, night sweats, and anorexia, and it often is associated with erythema nodosum or erythema multiforme. This disease commonly is found in the

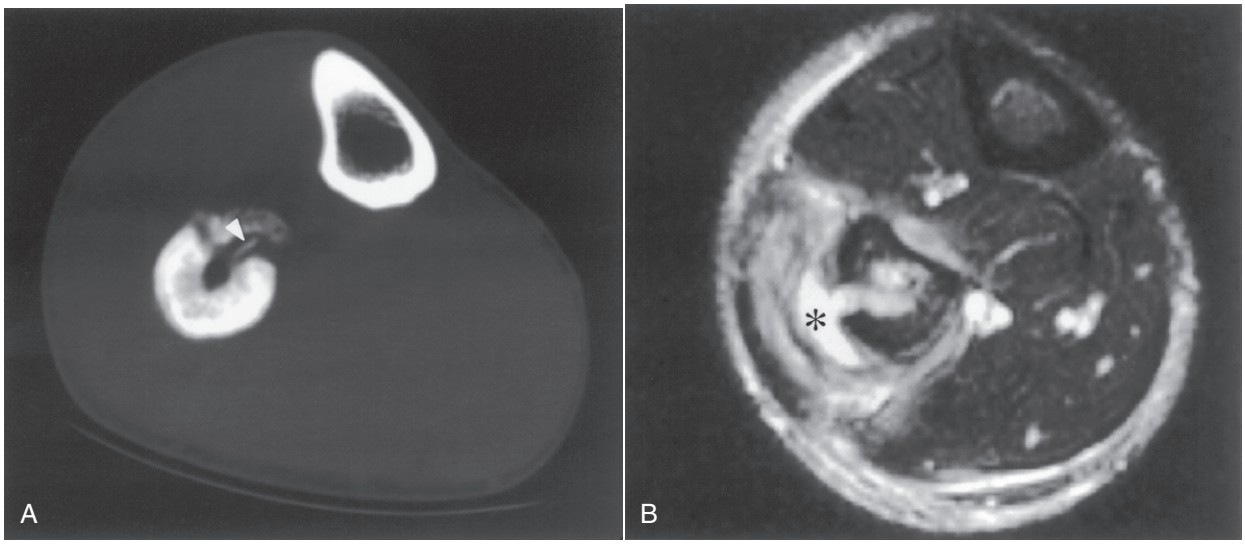

FIGURE 55-7 ■ Chronic osteomyelitis. **A,** CT reveals thickening of the fibular cortex and a sinus tract that contains a sequestrum *(arrowhead)*. **B,** T2-weighted axial MR image from a different level shows a lateral sinus tract through the cortex communicating with a soft tissue abscess *(asterisk)*. Edema is surrounding the entire fibula. (Courtesy Leanne Seeger, MD.)

southwestern United States. Extrapulmonary involvement is suggested by persistent high temperature and toxicity. *Coccidioides* osteomyelitis occurs primarily in cancellous bone (e.g., vertebral bodies, distal tubular bones, and the skull).[179] These lesions are not radiographically distinct from the lesions seen in osteomyelitis from other causes.[196] Débridement of bone lesions often is needed initially, and years of therapy are required. Oral triazole agents generally are recommended.[82]

Blastomycosis may mimic coccidioidomycosis, but the pulmonary involvement is much more varied, and fusion of the vertebral bodies rarely occurs. A propensity for the development of verrucous, reddened, weeping skin lesions has been noted, and prostate involvement may be seen. Bone involvement occurs frequently, with the skull and vertebral bodies being infected most often. Distinguishing it from other forms of osteomyelitis is impossible by radiographic examination.

Aspergillus osteomyelitis is generally a disease of immunosuppressed patients,[38] with *Aspergillus* pneumonia seen initially followed by disseminated disease. Bone disease occurring by hematogenous spread has developed, however, in normal individuals and after injectable drug use.[49,185] *Aspergillus* osteomyelitis developing after trauma also has been reported.

Other fungi are infrequent causes of osteomyelitis. The medical literature contains many reports of osteomyelitis caused by *C. neoformans*, generally in immunocompromised patients and in the setting of disseminated or pulmonary infection. The few reports in pediatric patients generally have involved immunocompromised adolescents. In adolescents and adults, usually only one bone is involved. The lesions generally are slowly destructive, very discrete lesions occurring primarily in the long tubular bones without marginal sclerosis. This radiologic reaction is confused most commonly with tumor and, occasionally, with tuberculosis. Infection of the ribs and skull also has been reported. Although experience with this disease is limited, débridement of the lesions and medical therapy seem to be highly effective.* Cases of *Rhizopus* osteomyelitis have been reported intermittently and apparently are hematogenous.[65]

CHRONIC OSTEOMYELITIS

Chronic osteomyelitis may develop after a surgical procedure, major trauma,[221] or unsuccessful treatment of acute osteomyelitis.[208] The diagnosis of chronic osteomyelitis usually is straightforward; patients generally have a painful, nonfunctional extremity and may have chronically draining sinuses. Radiographs often reveal clear evidence of devitalized bone, including the formation of sequestra or involucra. Cultures of the purulent exudate or necrotic bone usually reveal *S. aureus*, although gram-negative bacteria, including *H. influenzae*,[122] may be found in some cases. Plain radiographs, CT, and MRI all play roles in medical and surgical management by revealing details of the bony and soft tissue involvement, including the formation of abscesses and sequestra (Fig. 55-7).[45,177]

Treatment of chronic osteomyelitis involves the removal of devitalized bone, débridement and drainage of soft tissue disease, achieving wound closure and enhanced perfusion, stabilization of structural deficiencies, and long-term administration of appropriate antibiotics.[45]

Antimicrobial regimens for chronic staphylococcal osteomyelitis that have been studied include oral cloxacillin plus probenecid for 6 to 12 months; in this study 9 of 19 patients apparently were treated successfully.[18] In another study, the outcome of a 6-week course of nafcillin was compared with that of nafcillin and oral rifampin. No statistically significant differences were observed with the addition of rifampin, but most (10 of 17) of the patients showed no evidence of disease activity 2 years after the

*References 17, 33, 40, 92, 140, 141.

cessation of treatment with antibiotics.[168] The high failure rate in these and other studies has led to investigation of a variety of adjunctive measures to improve the outcome of chronic osteomyelitis. Local irrigation with antibiotic solutions, with[145] and without[6] added detergents, has been examined. Surgically implanted polymethyl methacrylate beads impregnated with an antibiotic (usually gentamicin, tobramycin, and vancomycin) are sometimes used for short periods to produce high local concentrations of drug[53] and then removed, although the added benefit from this approach is unclear.[20] Negative pressure wound therapy may also be used to achieve wound closure. Hyperbaric oxygen also has been suggested as an aid to therapy, but no comparative studies have been done.[161]

Because perpetuation of chronic infection seems to be caused by the presence of avascular bone and tissue, advances such as laser Doppler flowmetry ultimately may improve the outcome of this disease.[207] Surgical approaches to close open wounds after débridement and improve blood flow with mobilized tissue flaps also seem to bring about prolonged remission in some patients.[7] Meticulous surgical technique is essential to avoid thermal injury and to retain the vascular supply to compromised areas.[214] Complications of chronic osteomyelitis include secondary amyloidosis and local carcinomatous changes at the site of infection. The high likelihood of a poor outcome in chronic osteomyelitis and the complexities in its management must be kept in mind during treatment of acute hematogenous osteomyelitis.

CHAPTER 56

Septic Arthritis

Paul Krogstad

Acute infection of the joints can be caused by bacteria, fungi, and viruses. Bacterial infections occur most frequently. The terms *septic arthritis*, *acute suppurative pyarthrosis*, and *infectious arthritis* are used interchangeably with regard to bacterial infections and refer to the presence of organisms in the joint space.

EPIDEMIOLOGY

Septic arthritis occurs most frequently in childhood. The overall incidence of septic arthritis in children has been estimated as 5.5 to 12 cases per 100,000 individuals.[38] Describing the age distribution of septic arthritis is difficult because of the varying age intervals selected by authors of different studies. In a review from the preantibiotic era, half of the patients were younger than 20 years old.[52] In a later study, performed after antibiotics became available for systemic use, 31 of 66 patients (47%) were younger than 20 years old.[6] Septic arthritis occurs most often in boys and young children. Males are affected more often than are females by a ratio of 1.1 to 2.1 and most cases occur in children younger than 10 years old; a median age of 2 years has been reported in several series.*

PATHOPHYSIOLOGY

Synovial joints, also termed *diarthrodial joints*, are freely movable articulations containing synovia. Synovia is a transparent viscous fluid that lubricates the joint and nourishes the avascular articular cartilage. The synovium, a connective tissue layer interposed between the fibrous joint capsule and the fluid-filled synovial cavity, is responsible for formation of the joint fluid. The synovium contains a prominent capillary supply embedded in a connective tissue network containing at least two types of cells. One morphologic type (type A) seems to be related to mononuclear phagocytes; fibroblast-like type B cells seem to be responsible for the synthesis of hyaluronic acid. Joint fluid (synovia) is formed by filtration through the capillary network (i.e., the net balance of back-diffusion into the capillary bed and diffusion into the joint space). Diarthrodial joints normally contain small amounts of fluid (e.g., 0.5 to 3 mL in the knee),[93] with glucose and electrolyte concentrations equal to those in plasma. An oxygen partial pressure of 60 to 70 mm Hg, an albumin concentration of 10 to 20 g/L, and an IgG content of 500 mg/L are typical.[24,27,36,93]

Diffusion from the joint space is increased by any mechanism that increases pressure (distention with injected solution, active or passive motion, or external massage). Particulate material is removed from the joint space by synovial membrane macrophages and free monocytes (the latter usually are present in concentrations of $<60 \times 10^6$/L).[86] The viscosity of joint fluid is affected by the properties of hyaluronic acid; enzymatic depolymerization produces a viscosity approximately equivalent to that of water. With the loss of hyaluronidase from the synovia, the articular cartilage, with continued use, becomes eroded and sclerotic.[9] The vasculature of the synovial membrane is innervated, which has two consequences: joint pain is localized poorly because it results from stretching of the fibrous joint capsule, and inflammation within the joint cavity elicits an axon reflex leading to vasodilation and warmth over an infected joint. Lymphatic channels drain to the regional lymph nodes and are present in all the joint tissues except cartilage.

Microorganisms can enter the joint space by hematogenous spread, direct inoculation, or extension of a contiguous focus of infection. The synovial membrane has been shown to have circulatory perfusion similar to that of the brain (if one assumes that 1 g of synovial membrane is in an adult knee joint). Consequently, bacteria in blood are potentially delivered to the synovial membrane during transient bacteremia. A history of trauma often is cited as a predisposing factor for development of bacterial arthritis, but the significance of such a history is unclear in view of the great frequency of minor trauma in childhood.

Upper respiratory tract infections frequently precede the development of septic arthritis caused by *Haemophilus influenzae* type b and *Kingella kingae*, and oral ulcers are often noted prior to *Kingella* infections. Similar to traumatic injuries, they are presumed to increase the likelihood of bacteremia.[10,103] Septic arthritis also may develop after joint surgery and joint injections. Gram-negative organisms are the most frequent pathogens when septic arthritis occurs after surgery or instrumentation of the urinary or intestinal tract. *Salmonella* septic arthritis may develop during the course of *Salmonella* bacteremia in a normal host, but it occurs with increased frequency in patients with sickle-cell disease and related hemoglobinopathies. Although septic arthritis occurs in children and adults infected with human immunodeficiency virus (HIV),[68] as yet no data have substantiated that HIV increases the incidence of musculoskeletal infections in children. However, one recent report indicates that pneumococcal osteoarticular infections may be more common in HIV-positive children, compared with HIV-seronegative children.[85] Septic arthritis has been described during varicella, presumably caused by bacteremia resulting from infection of skin lesions. It must be differentiated from the apparent ability of varicella-zoster virus to cause joint inflammation on its own.[71,84] Arthritis also occurs during acute infection with other viruses (e.g., variola, Epstein-Barr virus, erythrovirus [parvovirus B19], mumps or measles viruses, and enteroviruses).

Inoculation arthritis occurs after invasion of the joint by a contaminated object. In one series, 5 of 35 cases of septic arthritis were caused by such a mechanism. A predilection for the knee exists; four of five cases cited in this study were secondary to kneeling on sewing needles.[88]

Aside from joint involvement during osteomyelitis, extension of a contiguous infection into the joint space rarely occurs. In one series, 10 of 77 patients with septic arthritis had disease originating from a contiguous focus.[20] None involved the joints of the foot, and eight occurred before the availability of many antibiotics (1951). This high frequency of septic arthritis caused by spread of infection from a contiguous focus has not been seen in more recent studies.

ETIOLOGY

Staphylococcus aureus is the most common agent causing septic arthritis, including methicillin-susceptible and methicillin-resistant *S. aureus* (MRSA).* Streptococci (especially group A beta-hemolytic organisms and pneumococci) have been responsible for most other gram-positive infections (Table 56-1). *K. kingae* has been recognized increasingly as a cause of septic arthritis,† perhaps because of improvements in laboratory methods.[105] In one series from Israel, *Kingella* was the most common bacterial isolate (48% of cases) and *S. aureus* was not found.[104] In neonates and sexually active adolescents with suspected septic arthritis, *Neisseria gonorrhoeae* should be considered.[41,58,60]

H. influenzae type b historically has been an important cause of septic arthritis in children younger than 2 years old but now is seen only rarely in areas with widespread immunization.[15,40,47,64] Arthritis caused by *Streptococcus pneumoniae* also generally occurs in children younger than 2 years old and may diminish in frequency with broader use of protein conjugate vaccines. In a few cases,

septic arthritis is seen with acute *Neisseria meningitidis* infection.

Salmonella spp. cause approximately 1 percent of the total cases of septic arthritis. Beyond the neonatal period, infections with other enteric gram-negative bacteria are rare occurrences in pediatric septic arthritis and often are associated with inoculation, instrumentation, or an immunocompromised state.[41] Infections with *Serratia*, *Aeromonas*, *Enterobacter*, *Bacteroides*, and *Campylobacter* generally occur in patients with malignancy who are immunosuppressed.* *Pseudomonas aeruginosa* infections are associated with arthritis in infants, with infection of puncture wounds, or with injectable drug use.[69,73,95] Discussion of Lyme arthritis is beyond the scope of this chapter, but intermittent, inflammatory arthritis is seen in many patients after *Borrelia burgdorferi* is transmitted by a tick bite.[56,92]

Unusual causes of septic arthritis include *Propionibacterium acnes*,[106] *Actinomyces* (formerly *Corynebacterium*) *pyogenes*,[77] and *Pasteurella multocida*.[44] *Streptobacillus moniliformis* infection of joints may become evident 2 to 3 days after a rat bite occurs; a macular rash commonly is present at initial evaluation. *Brucella*, mycobacteria (*Mycobacterium tuberculosis* and atypical species), and *Nocardia asteroides* may cause a chronic monarticular arthritis with a granulomatous reaction. Septic arthritis may also be caused during disseminated fungal infections, including histoplasmosis,[28] coccidioidomycosis,[13] blastomycosis,[73] and cryptococcosis.[91] The knee joint is most often involved in coccidioidal and cryptococcal arthritis.[13,91]

DIAGNOSIS

Clinical Findings

Almost all patients have fever and constitutional symptoms within the first few days of acquiring infection with the most common bacterial pathogens.[37] Table 56-2 lists the frequency of specific joint involvement in hematogenous septic arthritis of childhood. Lower extremity (knee, hip, and ankle) infections consistently account for approximately 80 percent of all cases.† Focal findings in the joint involved almost always are present.

In infants, in whom the hip is one of the most frequent joints involved, swelling, tenderness, and heat may be absent. Most commonly, the infant with septic arthritis lies with the involved leg abducted and externally rotated. Often, dislocation occurs.[75] When the capsule of the joint can be examined, swelling is noted; effusion was present in 22 of 24 cases in one series.[99] Because pain fibers are located in the capsule, any maneuver that increases intracapsular pressure also produces pain. In the hip, this pain can be elicited by compression of the head of the femur into the acetabulum. A portal of entry almost never is apparent, and bilateral hip joint infection may occur.[79] Pyogenic sacroiliitis often is accompanied by tenderness detected by pressure applied over the sacrum during a digital rectal examination and by pain experienced during simultaneous flexion, abduction, and external rotation at the hip.[2]

Gonococcal arthritis in neonates has nonspecific prodromal symptoms, including poor feeding, irritability, and fever. The exact portal of entry is unknown, and the joints below the hip usually are involved (knee, ankle, and metatarsal). During adolescence, gonococcal arthritis occurs as a manifestation of sepsis with fever, chills, rash, and multiple small joint involvement, often with tenosynovitis.[35] The illness frequently follows the onset of menses by a few days.

Radiologic Findings

Findings on plain radiography are due to capsular swelling. In the joints readily accessible to physical examination, radiographs add little to the diagnostic evaluation, but when septic arthritis of the hip is suspected in a child, they are a valuable adjunct and may identify other causes of hip pain, such as Legg-Calvé-Perthes disease, slipped capital femoral epiphysis, and fracture. Films of the hip should be made with the child in the frog-leg position and with the legs extended at the knee and slightly internally rotated. The early signs of septic arthritis are caused by swelling of the capsule, which displaces the fat lines. One of the oldest signs is the obturator sign: as the tendon of the obturator internus passes over the capsule of the hip joint, the margins of this muscle are displaced medially into the pelvis (Fig. 56-1).[53] With continued swelling of the hip joint capsule, the femoral head is displaced laterally and upward.[22]

*References 1, 6, 21, 41, 65, 73, 77.
†References 40, 52, 67, 69, 73, 88.

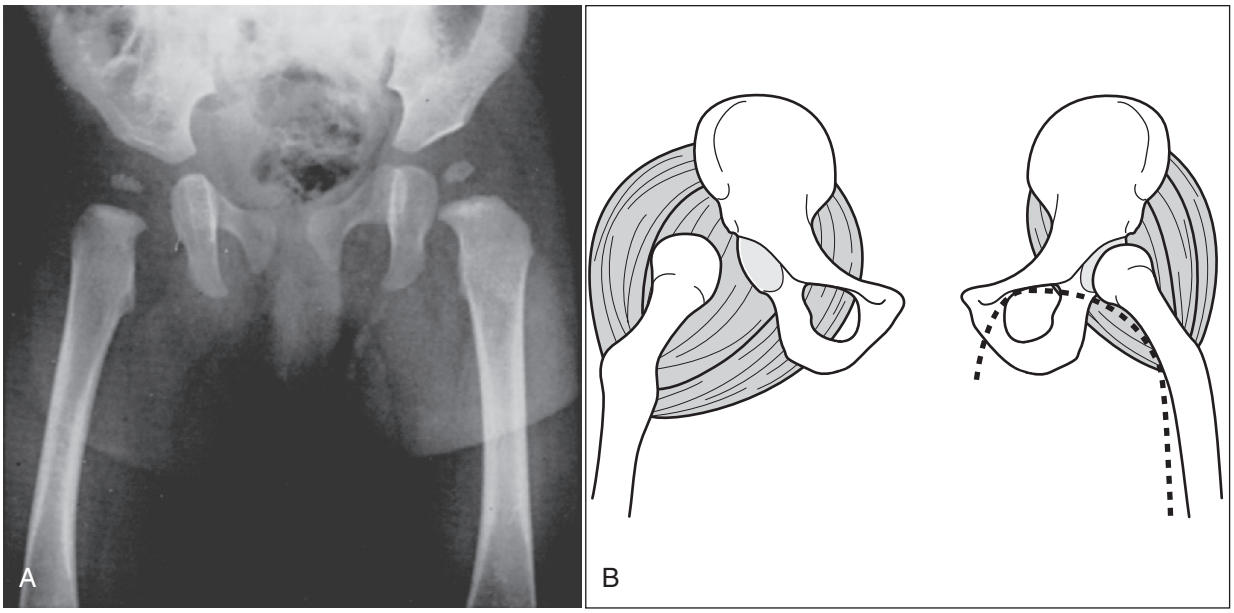

FIGURE 56-1 ■ The obturator sign in the hip is one of the oldest signs of septic arthritis. Another consistent finding is obliteration or lateral displacement of the gluteal fat lines and loss of continuity of the Shenton line. These findings are illustrated radiographically **(A)** and schematically **(B)**.

One of the most consistent findings is obliteration or lateral displacement of the gluteal fat lines (see Fig. 56-1).[101] Coincident with filling of the capsule with exudate, the femoral portion of the Shenton line is raised and its arc is widened.[101] If a technetium bone scan is performed, increased uptake on either side of the joint is seen during the "blood pool" phase of the scan.[98] Ultrasound evaluation has proved useful in evaluation of septic arthritis of the hip.[55,107] In a series of 96 patients, none of the 40 patients with normal ultrasound findings had septic arthritis.[107]

Bacterial infections causing pyogenic sacroiliitis may be particularly difficult to diagnose, because bone scintiscans and computed tomography initially may be negative. Magnetic resonance imaging seems to be the diagnostic radiologic method of choice.[2,31]

Laboratory Evaluation

Diagnostic evaluation for suspected septic arthritis generally includes determination of the erythrocyte sedimentation rate or C-reactive protein, and the peripheral blood leukocyte count and differential. These may be only mildly elevated in cases of proven infection, however.[30,107] Blood for culture always should be obtained because blood cultures sometimes may yield the pathogen when joint fluid cultures do not.[59]

Joint fluid should be collected in a heparinized syringe so that the large clot that usually forms in fluid obtained from patients with septic arthritis or juvenile rheumatoid arthritis does not preclude enumeration of leukocytes. A cell and differential count should be performed on aspirated joint fluid, and it must be Gram stained and cultured. Identification of organisms in joint fluid is the primary criterion for diagnosis of septic arthritis. Careful examination of a Gram-stained smear of joint fluid aspirates must be emphasized because joint fluid exerts a bacteriostatic effect on microorganisms and organisms that can be seen but may not grow in culture. Approximately 35 percent of joint aspirates are sterile in patients with other clinical and laboratory findings of a septic joint, including positive blood cultures.[10,73] Joint fluid should be cultured aerobically and under anaerobic conditions. The use of cell lysis culture bottles may enhance the recovery of *K. kingae* and other organisms.[105] *N. gonorrhoeae* is a highly fastidious organism, and oropharyngeal, rectal, and urogenital cultures or detection of gonococcal DNA in urine may be needed to confirm the diagnosis of gonococcal arthritis. Polymerase chain reaction analysis of joint fluid is likely to become a useful adjunct to the diagnosis of culture-negative disease, although it remains investigational.[70,96]

The median synovial fluid leukocyte count in bacterial arthritis in one study was 60.5×10^9 cells/L.[90] In this and other surveys,[86] polymorphonuclear leukocytes accounted for 75 to 90 percent of the white blood cells. Cell density generally is lower in fluid obtained from patients with acute rheumatic fever, juvenile rheumatoid arthritis, and other inflammatory causes of arthritis (Table 56-3).[8,86,90] The glucose concentration often is decreased in septic arthritis, but it may be normal.[90,99] It also may be depressed in rheumatoid arthritis and other conditions. A joint fluid leukocyte density of 5 to 8×10^9 cells/L has been found in joint fluid from patients ultimately proved to have septic arthritis.[86] Minimally turbid fluid with a seemingly low number of cells still should be processed for bacterial culture and Gram stain. Examination of the fluid for uric acid and other types of crystals should be considered in certain children (e.g., children with hyperuricemia).

TABLE 56-3 **Joint Fluid Findings in Childhood Arthritides**

Diagnosis	Spontaneous Clotting	Mucin Clot	Leukocytes/mL	% Polymorphonuclear Leukocytes	Glucose as Percentage of Blood Value

Juvenile rheumatoid arthritis	Large clot	Small, friable masses	15,000	60	75

From Ropes M. Joint fluid findings in disease. Bull Rheum Dis *1957;***7***(Suppl.):21.*

DIFFERENTIAL DIAGNOSIS

Although bacterial infections are the most common cause of septic arthritis, other microorganisms, including viruses (varicella-zoster, erythrovirus [parvovirus B19], rubella, chikungunya[62] and other togaviruses, variola, vaccinia, certain enteroviruses, others), mycobacteria, and fungi (*Coccidioides* spp., *Sporothrix schenckii*, *Blastomyces dermatitidis*, *Candida* spp.), may be involved.

The differential diagnosis includes infectious and noninfectious entities. Local infections that mimic septic arthritis include obturator internus muscle abscess,[97] epiphyseal osteomyelitis, a deep cellulitis, and, rarely, septic (suppurative) bursitis. Septic bursitis may be particularly difficult to distinguish from septic arthritis. Children with septic bursitis frequently have a history of recent trauma and fever along with limitation of joint movement.[51,81] Careful physical examination and aspiration of bursal fluid allow the entities to be differentiated. Septic arthritis and arthralgia may occur during infectious endocarditis.

Toxic (or transient) synovitis (also referred to as irritable hip and reactive synovitis) is frequently seen in children and has milder presenting features than bacterial infections of the hip. The combination of fever, elevated white blood cell count, erythrocyte sedimentation rate (>40 mm/hr), C-reactive protein, and inability to bear weight permits septic arthritis to be distinguished from transient synovitis with high accuracy; greater than 90 percent sensitivity for the detection of septic arthritis has been reported when all of these factors are present.[17,30,59,107]

Other noninfectious entities to be considered in the differential diagnosis include traumatic arthritis, juvenile idiopathic arthritis, villonodular synovitis, leukemia, serum sickness, ulcerative colitis, granulomatous colitis, Schönlein-Henoch purpura, traumatic arthritis, fracture, Legg-Calvé-Perthes disease, slipped femoral capital epiphysis, and metabolic diseases affecting joints (e.g., ochronosis in adults with alkaptonuria).

TREATMENT

Surgical Treatment

In infants, septic arthritis in the hips or shoulders is a surgical emergency; these joints should be drained as soon as the diagnosis is apparent to prevent bony destruction.[79] In a study in adults, the outcome of septic arthritis was better in patients treated by repeated needle aspiration than in patients treated by surgical drainage.[42,43] Eighty percent of the patients treated by needle aspiration were thought to have a good outcome versus 47 percent treated by surgical drainage. All wrist joint infections in this series were treated only by needle aspiration; in treatment of septic arthritis of the knee, however, the outcome was almost equivalent. Similar findings have been reported by others.[11] The investigators suggested that surgical drainage should be performed in any joint whenever the presence of large amounts of fibrin, tissue debris, or loculation prevents adequate drainage by needle aspiration.

Antibiotic Therapy

Antibiotic treatment of septic arthritis should target the most common pathogens. In children beyond the neonatal period, *S. aureus* and other gram-positive organisms currently predominate.[15,64,73] Antistaphylococcal penicillins (e.g., oxacillin or nafcillin) are usually given, but vancomycin or clindamycin should be used as the empirical antistaphylococcal agent in areas where community-acquired MRSA is a concern.[3,66] Some authorities advocate that this be done when community-acquired MRSA represents more than 10 percent of *S. aureus* in a geographic area.[57] Vancomycin is preferred if clindamycin resistance is common among *S. aureus* isolates (>10%). At present, no regimen is clearly preferred for the treatment of penicillin-nonsusceptible *S. pneumoniae*, but ceftriaxone, cefotaxime, and clindamycin have been used successfully.[16]

The need for coverage for gram-negative pathogens should also be considered. Ceftriaxone and cefotaxime are appropriate for the treatment of gonococcal infection. In children below the age of 36 months,[32] adding empirical coverage for *Kingella* infection may also be indicated if Gram stain and culture have not identified an alternative pathogen; cefuroxime, cefotaxime, or ceftriaxone may be preferred.[102] Although the risk of acquiring invasive *H. influenzae* type b infection is low in areas with effective immunization, rare cases continue to be reported. Children younger than 2 years who have not been immunized against *H. influenzae* type b should be treated initially with a regimen that contains an antistaphylococcal agent, such as nafcillin, vancomycin, or clindamycin, and an agent active against this agent (e.g.,

cefotaxime). Cefuroxime, which is active against *S. aureus* (and other gram-positive pathogens) and *H. influenzae*, is a useful alternative.

All antibiotics that have been studied penetrate into joint fluid readily; soon after administration, at the time of peak serum levels, the joint fluid concentration averages 30 percent of the serum value.[5,7,72,83] The efflux of antibiotic from joint fluid back to serum is slow, however. Immediately before the next systemic dose is administered, joint fluid antibiotic concentrations frequently exceed the concentrations present in serum. Antibiotics, whether administered orally or parenterally, can achieve efficacious concentrations in joint fluid.

Injecting antibiotics into the joint space usually is unnecessary because of their excellent penetration. Many antibiotics (e.g., cephalothin) are capable of evoking an intense inflammatory reaction, much as they do if they are infiltrated beneath the skin. Tetzlaff and associates[94] have shown that septic arthritis can be treated for 1 week (or less) parenterally, with the balance of the drug given orally. These investigators considered the minimal duration of therapy to be 3 weeks, because some cases initially thought to reflect septic arthritis alone may actually have coincident bone infection.

The effectiveness of antibiotic therapy can be assessed by serial joint fluid examinations, leukocyte density, and culture results.[99] The time required for resolution of joint symptoms and the time for the synovia to become sterile are proportional to the duration of symptoms before the initiation of appropriate antibiotic therapy.[54] In one study, some patients still had cultures yielding bacteria after undergoing 1 week of therapy. In these patients, cellular density ranged from 25 to 253×10^9 cells/L (mean 109×10^9 cells/L) at the beginning of therapy; 92 percent of the cells were polymorphonuclear leukocytes. By the end of 2 weeks of therapy, all cultures were sterile, and leukocyte density ranged from 4.9 to 23×10^9 cells/L (mean of 12.3×10^9 cells/L).[99] Similar studies of the rate of resolution of indicators of inflammation in joint fluid have suggested that after receiving 9 days of treatment, patients who ultimately recovered completely had a density of 5×10^9 cells/L; however, in patients with recrudescent infection or a poor outcome, the density was 6×10^{10} cells/L.[41]

When an effusion reaccumulates, one should remove it by arthrocentesis, not only to make the patient more comfortable but also to permit serial assessment of therapy. Generally, disease caused by *S. aureus* and Enterobacteriaceae requires longer treatment than disease caused by *H. influenzae* or meningococci. Radiographs should be obtained during therapy to seek bone changes indicating that osteomyelitis may have been present. Concomitant osteomyelitis may require surgical intervention, and antibiotic therapy must continue beyond 21 days.

PROGNOSIS

Sequelae, including hip dislocation, are more likely to develop in infants and patients with symptoms of longer duration.[99,100] In one study, seven of eight patients in whom "permanent" hip dislocation developed had symptoms for 7 or more days before receiving treatment.[100] Similarly, all patients with spontaneous ankylosis had symptoms longer than 7 days.[100] Comparable data were obtained by Samilson and colleagues.[88] Eight of 10 patients with pathologic dislocation of the hip had symptoms for longer than 7 days.

A detailed analysis of factors affecting satisfactory outcomes in hematogenous septic arthritis of childhood showed no significant difference in the joint when arthrotomy, with or without irrigation, was compared with repeated aspiration.[69] Likewise, the specific antibiotic used had no effect on outcome as long as it was effective against the infecting organism. The literature does suggest that septic arthritis caused by Enterobacteriaceae is associated with more frequent sequelae than when caused by other pathogens.[43,74] *S. aureus* is more likely to cause sequelae than *H. influenzae*.[10]

A randomized, placebo-controlled study has examined the impact of a brief course of dexamethasone on the outcome of bacteriologically confirmed cases of septic arthritis of hematogenous origin in children. Children younger than 3 months were excluded from participation, and *H. influenzae* was responsible for 13 percent of cases among the 100 evaluable patients. After 1 year of follow-up, limping, joint pain, and restriction of movement were found in 26 percent of patients who received a placebo, but in only 1 of 50 patients treated with dexamethasone.[80] A second randomized trial involved 49 children (average age of 33 months) with septic arthritis to whom adjunctive dexamethasone was given during the first 4 days of antimicrobial therapy.[50] This treatment was associated with decreased duration of fever (1.7 vs. 2.8 days), pain (7.2 vs. 10.8 days), and parenteral antibiotics (9.9 vs. 12.6 days), but no difference in long-term outcome. At present, the benefits of dexamethasone therapy in septic arthritis remain unclear.

SPECIAL PROBLEMS

Neonatal Septic Arthritis

Neonatal septic arthritis is a problem that warrants special attention because of its subtle signs and symptoms,[23] its potential for catastrophic consequences of untreated disease,[78] and the unusual organisms occasionally seen. Any neonate who has swelling in the region of the thigh and the buttock and holds that leg flexed with slight abduction and external rotation at the hip should be suspected to have femoral-acetabular septic arthritis. It can occur 1 to 28 days after femoral venipuncture (in most neonates, 5 to 9 days) and should not be confused with femoral vein thrombosis.[4,19]

In most neonates, no toxemia, fever, or leukocytosis is present. More than one joint may be involved when initially evaluated. The progression of disease in neonates can be so indolent that the hip spontaneously drains along the obturator internus, and the condition is manifested as a lower abdominal mass just above the inguinal canal.[34] Problems in recognizing the disease in neonates undoubtedly contribute to the poor outcome. In one

series, the delay from onset to diagnosis was an average of 1 week; only two of the nine infants in this series had a normal hip examination at follow-up.[78]

In most series, the causative agents are staphylococci and streptococci,[4,14,19,23,78] but gram-negative organisms often are found. More importantly, arthritis caused by *Candida albicans* has been described,[26] and the gonococcus should not be forgotten. In gonococcal arthritis, the symptoms, which usually become apparent in infants 1 to 5 weeks of age, generally are polyarthritic (more than one joint involved).[39] As previously noted, other symptoms of neonatal gonococcal arthritis are no different from symptoms caused by other pathogens.

Initial antibiotic therapy for neonatal septic arthritis should be directed toward *S. aureus* and the nosocomial gram-negative bacteria that are prevalent in the nursery. Antibiotic therapy can be altered when the susceptibility of the causative bacterium is known. As noted earlier, the usual duration of therapy is 3 to 4 weeks, and radiography should be performed toward the end of treatment. Oral therapy has been used successfully to complete treatment of septic arthritis in neonates,[82] but absorption of antibiotics in this age range is unpredictable.[89]

Fungal Arthritis

Fungal arthritis is rare in children but may be seen with pathogens of endemic mycoses, such as *Histoplasma capsulatum*, *B. dermatitidis*,[73] and *Coccidioides* species, as well as with opportunistic fungal pathogens (e.g., *Candida* spp., *Cryptococcus neoformans*).[67,91] These pathogens usually manifest after an indolent course. The recommended medical treatment is generally identical to that required for other systemic infections caused by these organisms.

Joint Infections During Rheumatoid Arthritis

Joint infections that develop during a case of rheumatoid arthritis seem to occur more frequently in adults with rheumatoid arthritis than in children. In one series, only 2 of 17 patients were younger than age 10 years.[6] The notable features are that the hips generally are not involved and infection of multiple joints (17 of 44 patients had more than one joint involved) frequently occurs. Because of the preexisting joint disease, the diagnosis often is delayed and the outcome usually is poor. Septic arthritis should be considered if an unusual worsening of one joint occurs during a flare of rheumatoid arthritis.

Reactive Arthritis

An oligoarticular arthritis may occur after infection with *Shigella* spp.,[18,76] *Chlamydia trachomatis*, *Salmonella* spp.,[49] and certain *Yersinia* serotypes.[61] A link to infection with *Chlamydophila pneumoniae* (formerly *Chlamydia pneumoniae*) has also been described, and rare cases of septic arthritis may follow *Clostridium difficile* colitis in children.[12,25,33,63] This postinfectious joint inflammation seems to develop with greater frequency in individuals who express the histocompatibility antigen HLA-B*27, perhaps as a result of molecular similarities between bacterial antigens and the human protein. In addition, during the initial infection, bacterial antigens apparently may be deposited in the synovium and may persist, leading to pathogenic inflammation.[46,61]

Generally, the onset of joint symptoms occurs a few days to several weeks after a transient, and often mild episode of diarrhea or symptoms of urethritis. The arthritis may mimic rheumatic fever and is characterized by daily low-grade fever and an increased erythrocyte sedimentation rate. Classic Reiter syndrome, which includes ocular inflammation, oligoarticular arthritis, and sterile urethritis, may also occur.

Reactive arthritis generally can be distinguished from septic arthritis by analysis of synovial fluid; infectious arthritis usually is associated with an increased number of white blood cells in the synovial fluid.[8] Resolution of joint symptoms in cases of reactive arthritis usually occurs several weeks to months after onset. Anti-inflammatory agents are the cornerstone of therapy and may include nonsteroidal anti-inflammatory drugs, corticosteroids, or disease-modifying antirheumatic drugs.

Reactive arthritis also may occur after acute infections with *N. meningitidis*[48] and *H. influenzae*.[87] Symptoms and signs of joint inflammation often appear 1 week or more after the acute septic episode and resolve without sequelae.

CHAPTER 57

Bacterial Myositis and Pyomyositis

Charles Grose

Myositis is not a common manifestation of bacterial infection, but when it occurs, the consequences to the patient may be severe or even fatal. *Staphylococcus aureus* and group A streptococci are the most likely causative organisms. Myositis also has been associated with several other infectious agents, including viruses, fungi, and parasites. These pathogens are listed in Table 57-1; they are discussed briefly in this chapter and more thoroughly in the chapters on the specific microorganisms. This chapter focuses on two forms of pyogenic myositis, sometimes differentiated as *acute bacterial myositis* and classical (or *tropical) pyomyositis*. The former is caused primarily by group A streptococci and the latter by *S. aureus*, including methicillin-resistant *S. aureus* (MRSA).

PYOMYOSITIS

The pathologic entity termed *spontaneous acute myositis* was recognized by Virchow in the mid-19th century, but the first clinical description of suppurative myositis generally is attributed to the Japanese surgeon Scriba.[21] In 1904, another Japanese surgeon, Miyake,[17] extensively reviewed the subject of skeletal muscle abscesses and added 33 more cases. As the British and French expanded their colonial empires at the turn of the 20th century, the disease was recognized with increasing frequency in the native populations and in the soldiers who lived in the tropical areas of Asia and Africa.[26] It acquired the name by which it now is known widely—*tropical pyomyositis*.[9,10]

The suitability of this designation was confirmed by an epidemiologic study in East Africa, which discovered that the disease was found commonly only in regions with a truly tropical climate (i.e., a fairly constant high temperature and high relative humidity) at an altitude below 4000 feet.[15] Pyomyositis has been described, however, in children from geographic regions of the United States as diverse as New England,[9] northern California,[2] Iowa,[16] and Texas.[11,19,22] Numerous reported cases within the continental United States have occurred in and around San Antonio, Texas.[5] In a 10-year chart review, one or two cases of pyomyositis per 4000 pediatric admissions occurred annually. In contrast, a review of consultations of pediatric infectious diseases at the University of Iowa Hospital disclosed fewer cases of pyomyositis among children younger than 16 years old.[7] Pyomyositis seems to occur more commonly in children who live in the southernmost regions of the United States (e.g., Texas) than in children who live in the northern regions (e.g., Iowa).

Pathophysiology

The etiologic agent of the skeletal muscle abscesses in more than 90 percent of cases is *S. aureus*. An increasing percentage are caused by community-associated MRSA.[28] A distant second bacteriologic isolate is *Streptococcus*, including group A and nonhemolytic strains.

Miyake[17] studied extensively the experimental conditions under which *Staphylococcus* spp. cause muscle abscesses. When healthy rabbits were given boluses of *Staphylococcus* intravenously, they occasionally developed small abscesses in the kidney, liver, or spleen but never in the skeletal muscles. When specific muscles were damaged by mechanical pinching or electric current 24 or 48 hours before the intravenous injection of bacteria was administered, small abscesses developed within 2 to 28 days at some of the injured sites in nearly half of the animals. Abscesses were not found in healthy muscle tissue.

The role of trauma was supported further by a study of pyomyositis in the British Army.[3] After physicians found this disease to be a common problem in Gurkha army recruits, they investigated 32 cases and made several observations. Two thirds of the men recalled having experienced trauma at the affected site, the incidence of abscesses increased as the severity of physical training increased, and the abscesses occurred three times more commonly on the dominant (right) side of the body. In an analysis of 78 cases in Uganda, abscesses also were found more commonly on the right side of the body.[15]

From experimental evidence and clinical observations, two conditions commonly are found when pyomyositis occurs: muscle injury and bacteremia, usually staphylococcal. A reported case is illustrative.[11] A 12-year-old girl caught her left foot in the wheel of a moving bicycle and tumbled to the ground. One week later, she developed a furuncle of the foot, and within the next 2 weeks she developed painful lumps in muscles of the thigh, shoulder, and chest wall (which had been injured during the original accident). Cultures from the furuncle and blood and from the incised muscle abscesses grew *S. aureus*. The initial episode of trauma resulted in a staphylococcal skin lesion and, presumably, a bacteremia that seeded sites of previously bruised muscle.

Seven children with pyomyositis are described in Table 57-2. An analysis of all seven cases illustrates the association of pyomyositis with trauma. The sources of muscle trauma have ranged from bicycle accidents to strenuous aerobic exercises. These cases also may explain the predilection of the disease to occur in warmer climates; concomitant skin infections and muscle trauma

are more likely to occur in a climate in which children can play or work outside wearing fewer clothes for most of the year. One predisposing disease not listed in Table 57-2 is varicella (chickenpox), in which muscle abscesses are secondary to bacterial invasion via the skin vesicles.[12]

In tropical countries, pyomyositis is said to occur in individuals who are malnourished and who have multiple parasitic infections. This association has not been confirmed, however, in children with pyomyositis seen in the United States or Australia.[5,7,13] The children have not been malnourished or vitamin-deficient, and they have not had parasitic infestation or marked eosinophilia. Extensive immunologic evaluations also have been normal; the tests included quantitative immunoglobulins, enumeration of T-lymphocyte subpopulations, total hemolytic complement levels, and leukocyte function as tested by reduction of nitroblue tetrazolium.

Clinical Presentation

Pyomyositis often is considered a disease of adolescents and young adults, even though it occurs in individuals of all ages, including infants and young children.[2,6,13] Boys are affected more often than girls. As more girls enter competitive sporting activities, however, pyomyositis is being reported in female athletes.[16] Most children with pyomyositis have a solitary lesion, but multiple lesions are common findings. The most common site of abscess formation is the thigh, followed by the calf, buttock, arm, scapula, and chest wall. The muscle lesions are firm or "woody" to palpation, with a well-defined border. The sign of fluctuation may be difficult to elicit. Erythema and warmth often are not apparent because of the deep location of the masses, although diffuse tenderness usually occurs. When a muscle in an extremity is involved, the entire limb may be swollen. Occasionally, pyomyositis also can occur in muscles of the pelvis, in which case pain may be transferred to the hip.[14,19]

In case reports with a clinical history, children with pyomyositis often had similar presenting complaints.[7,11] Many had incurred a recent accidental injury (often involving a leg) that usually was not considered serious. After a few days, the children developed low-grade fever, muscle pain, and, occasionally, an impaired gait. These symptoms persisted a few days to a few weeks until a mass appeared. When first examined, many of the patients were considered to have only a contusion or a hematoma; occasionally, a child was diagnosed as having a rhabdomyosarcoma. Although the disease usually occurs in individuals who are otherwise healthy, pyomyositis has been reported in patients with malignancy. Pyomyositis also may develop in children with acquired immunodeficiency syndrome or other immunodeficiency.[13] The pathophysiology of pyogenic muscle abscess may not be the same, however, in immunodeficient individuals with increased susceptibility to bacterial infection. Most children with pyomyositis have no definable immunologic abnormalities.

An unusual clinical presentation is acute abdominal pain. Beck and Grose[5] described two children with pyomyositis whose initial complaints were confined to the abdominal wall. One patient, a 6-year-old child, had been struck in the abdomen in a mock fistfight with an older sibling. One week later, he developed a low-grade fever

and began to walk with a stoop; after another week, his mother detected a "knot" in his right mid-abdominal wall. The second case involved the 11-year-old son of a rancher; the boy was struck in the abdomen by a bale of hay tossed from a hay baler. When he subsequently developed symptoms of abdominal pain, the diagnosis of appendicitis was entertained. When a mass later became palpable in his abdominal wall, rhabdomyosarcoma was suspected. A correct diagnosis was made after the use of scintigraphy and sonography.[5] A review from Nigeria found muscle abscesses in the anterior abdominal wall to be common.[2]

Diagnosis

The diagnosis of pyomyositis should be considered in any child with fever and muscle pain, especially if a recent history of trauma exists. When a child has visible masses at commonly involved sites, such as the thigh, the diagnosis of pyomyositis can be made by needle aspiration of a mass. If a febrile child complains of myalgia in an extremity but has no palpable masses, the differential diagnosis must include more common inflammatory and infectious conditions of the bone or joint. A definitive diagnosis usually depends on one or more radiologic procedures. Plain films may show a soft tissue swelling or even a widened fascial plane suggestive of a mass lesion. A combination of plain radiography and magnetic resonance imaging (MRI) often can exclude osteomyelitis and pyoarthritis. If the diagnosis still is in question, scanning with a radioactive tracer can localize a muscle abscess precisely and visualize other intramuscular abscesses too small to palpate (Fig. 57-1). Alternatively, ultrasonography can detect muscle abscesses and may be preferable as an initial procedure because it avoids the radiation exposure from computed tomography (CT) or scintigrams (Fig. 57-2).[27]

MRI is very helpful in delineating the extent of a muscle abscess. In many cases, the abscess is much larger than suspected by physical signs and symptoms. The MRI scans of an illustrative case are presented in Figure 57-3. The patient was a 17-year-old girl with a swollen left lower thigh. She worked part-time as an attendant in an athletic club, where she participated in some of the vigorous exercise programs. Radiographs of the knee were normal, whereas a technetium bone scan showed slightly increased radionuclide uptake in the soft tissues around the distal left femur. MRI of the left and right thighs showed a large fluid collection extending from the middle to distal left femur. Surgical exploration identified extensive abscess formation around the posterior aspect of the femur; the culture grew *S. aureus*. The affected muscle groups included the vastus medialis, vastus intermedius, vastus lateralis, and biceps femoris. The bone was not involved. For the reasons described, MRI has become the preferred procedure for establishing the diagnosis of pyomyositis.[14,23,27]

Treatment

Because pyomyositis is an abscess of skeletal muscle, the treatment is surgical incision and drainage.[2] Several

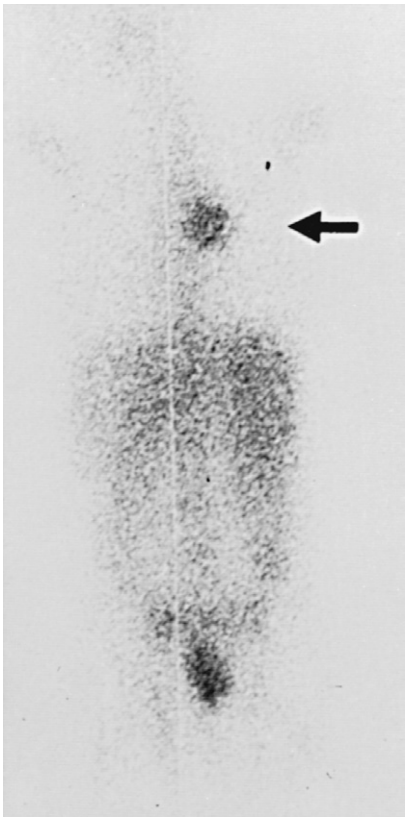

FIGURE 57-1 ■ Scintigram of a patient with pyomyositis. Radiopharmaceutical scan shows abnormally high uptake over the right scapula *(arrow),* where an abscess cavity was located within the muscle. Increased radioactivity also is observed in the bladder, which is a normal finding.

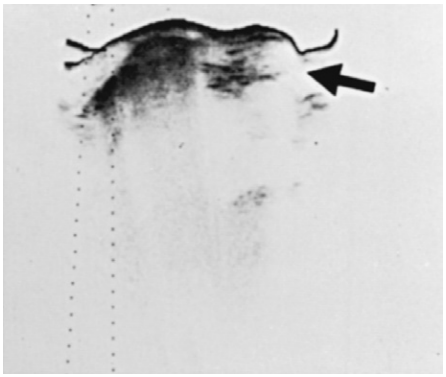

FIGURE 57-2 ■ Sonogram of the abdominal wall of a patient with pyomyositis. The transverse view of the abdomen shows an abscess cavity in the right belly of the rectus abdominis muscle *(arrow).*

physicians have seen that smaller lesions resolve spontaneously, even before the antibiotic era. An important role for systemic antibiotics is to prevent the formation of further muscle abscesses, especially in a patient with proven bacteremia. Because *S. aureus* is the most likely agent, a semisynthetic penicillinase-resistant penicillin is the preferred antibiotic in communities with relatively little MRSA. Usually, nafcillin or oxacillin 150 to 200 mg/kg is administered intravenously every 6 hours. When

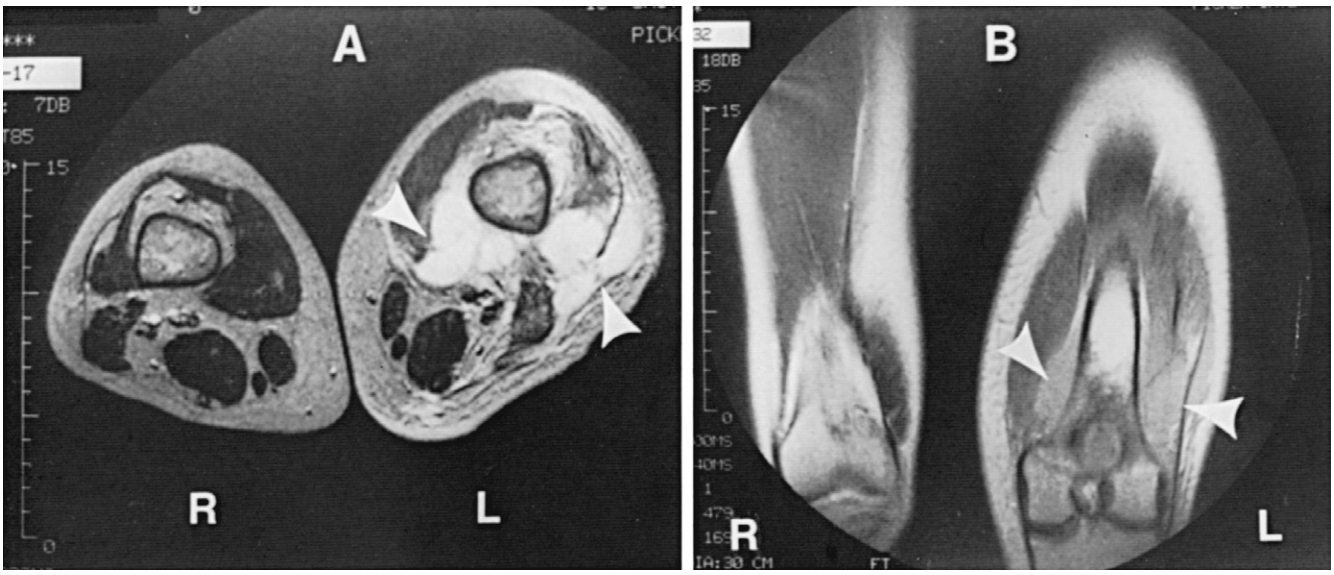

FIGURE 57-3 ■ Magnetic resonance imaging of the thighs of a patient with pyomyositis. **A,** Axial images of the right (*R*) and left *(L)* thighs. **B,** Coronal images around the distal femoral shafts and femoral condyles. The scans show several well-defined areas of extremely high intensity in the muscle bundles and fascial planes from the middle to distal left femur *(arrows).* The high signal intensity suggests a fluid collection (e.g., an abscess), rather than a neoplastic process. Edema of the subcutaneous tissues also is evident in the lateral aspect of the swollen left thigh. There are no abnormal signals within the bone.

pyomyositis occurs in a patient with penicillin hypersensitivity, clindamycin 40 mg/kg/day divided every 8 hours can be substituted because of its excellent coverage of gram-positive cocci. Parenteral therapy is continued until clinical improvement is evident, usually within a few days after surgical drainage. Thereafter, the antibiotics can be given orally for an additional 2 to 3 weeks.[20] A cephalosporin (cephalexin 100 mg/kg/day) or clindamycin 30 to 40 mg/kg/day is acceptable.

In many communities, MRSA is now a common agent.[28] In a clinical analysis of 182 patients with pyomyositis from Texas Children's Hospital in Houston, more than 50 percent of the isolated *S. aureus* strains were MRSA.[19] In these communities, initial antibiotic management must include either intravenous clindamycin or vancomycin 60 mg/kg/day divided every 6 hours. In adolescents the dosage of vancomycin is usually reduced to 45 mg/kg/day, divided every 8 hours. Clindamycin can be continued as an oral antibiotic. For MRSA isolates resistant to clindamycin, treatment with intravenous vancomycin can be followed by administration of oral linezolid 30 mg/kg/day divided every 8 hours for children younger than 12 years; for children 12 years and older, 20 mg/kg/day divided every 12 hours is given. Therapy of MRSA infection may require a longer duration, from 3 to 4 weeks. Before discontinuing antibiotics, the patient should have documented normal levels of C-reactive protein and erythrocyte sedimentation rate.

ACUTE BACTERIAL MYOSITIS

Far less common than classical (tropical) pyomyositis is acute bacterial myositis, usually caused by group A streptococci. In this condition, the bacterial infection often is not confined to distinct abscesses within the muscle, but instead it extends diffusely through one or more muscle groups. As with pyomyositis, the disease occurs more commonly in males than in females and usually is associated with prior physical exertion and perhaps minor trauma. In contrast to pyomyositis, most published cases of acute bacterial myositis have occurred in adults and not in children.[4] The disease has been divided by Svane[25] into the following four main types:

1. A malignant form with septicemia and a uniformly fatal outcome
2. An acute form with a more protracted clinical course and other foci, such as the bones, joints, or viscera
3. A subacute form with a better clinical prognosis
4. A benign type associated with more distinct muscle abscesses

The benign type of acute bacterial myositis by the Svane classification is the same disease process as described in the preceding section on pyomyositis.

Clinical Presentation

The main clinical difference between the acute myositis syndrome and the pyomyositis syndrome is the virulence of the former disease, especially the malignant type. A case in a San Antonio, Texas, native is illustrative. The patient was a 23-year-old jackhammer operator who was admitted because of high fever, malaise, and pains in his arms. On examination, both upper extremities were tender to palpation, and faint erythema was visible over the same areas. He soon became incoherent, and his general condition quickly deteriorated. Death followed within 24 hours. Blood cultures drawn before death grew group A streptococcus, and cultures of the biceps muscles obtained at autopsy grew the same organism. This case is similar to others described in the literature.[4,25] The

patient presumably would incur considerable minor trauma to the muscles of the upper arms and shoulders from his work as a jackhammer operator. Two reported cases of streptococcal myositis in children involved the left thigh and the left paravertebral muscles.[18] The first child developed septic shock and required intensive care for 27 days before a definitive diagnosis was made by CT.

A case of generalized myositis with staphylococcal septicemia has been described in a 15-year-old boy.[1] The patient presented with signs of fever and very diffuse muscle swelling and tenderness. All muscle groups of the extremities appeared to be inflamed and markedly tender; the creatine phosphokinase enzyme levels were markedly elevated. Culture of a muscle biopsy specimen grew *S. aureus*, as did previously drawn blood cultures. The patient experienced a stormy hospital course with severe hypotension and shock syndrome, requiring treatment with intravenous fluids, corticosteroids, dopamine, heparin, and assisted ventilation. He also received a total of 4 weeks of antistaphylococcal antibiotic therapy.

Diagnosis

Blood cultures are positive most often in patients with the most significant clinical symptoms. Cultures of muscle biopsy specimens may yield a profuse growth of bacteria. Rarely, myositis has occurred as a delayed complication of chickenpox, often together with fasciitis.[12,17,23] In this situation, bacteremia may not be documented because the bacterial process usually is the result of contiguous spread from a secondarily infected pock lesion. These streptococcal complications of chickenpox often occur in an extremity, which may become swollen and painful. Under these circumstances, MRI can be an extremely valuable diagnostic tool to gauge the depth and extent of inflammation.[27]

Treatment and the Eagle Effect

The treatment of acute streptococcal or staphylococcal myositis of the malignant type is a medical emergency. As soon as the diagnosis is suspected, bacteriologic cultures should be obtained and intravenous therapy should be initiated with a high-dose semisynthetic penicillin (e.g., nafcillin 50 mg/kg every 6 hours) and vancomycin. If the cultures yield group A streptococci rather than *Staphylococcus*, the antibiotic can be switched to penicillin G at an equivalent high dosage. Surgical consultation is required to evaluate the need for débridement and drainage. Obtaining MRI scans may be advisable to document the extent of the disease and the response to antibiotic therapy. In severe cases of bacterial myositis, the total duration of hospitalization can exceed 4 weeks.[1,18]

The apparent resurgence of serious streptococcal infection has led to an increased interest in what has been called the *Harry Eagle effect*, named after the scientist who first described the failure of penicillin to eradicate group A streptococcal infection in a mouse model.[8] Eagle inoculated mice intramuscularly with group A streptococci and observed a markedly retarded bactericidal action of penicillin on organisms in the older abscesses, even though the bacteria remained highly sensitive to the antibiotic. Even massive doses of penicillin 10,000 times greater than the minimum inhibitory concentration were not effective at eradicating the bacteria. Subsequent studies by other investigators confirmed the existence of the Eagle effect and disclosed that clindamycin showed superior efficacy to penicillin in treatment of streptococcal myositis in the mouse model.[24] These physicians observed that penicillin most likely fails to kill stationary-phase streptococci in muscle infections, an explanation for the Eagle effect. They suggested that streptococcal myositis or fasciitis be treated with intravenous clindamycin 40 mg/kg/day, if the condition fails to respond to penicillin therapy.

Miscellaneous Causes of Myositis

Viral infection occasionally leads to myositis (see Table 57-1). The most common example undoubtedly is myositis associated with influenza virus infection in children. Typically, school-aged children are affected. Muscle groups of the legs often are involved, associated with a marked elevation of serum creatine phosphokinase. Clinical symptoms generally last 2 to 4 days. Another, far less common myositis is caused by coxsackievirus B infection. This disease is termed *epidemic pleurodynia* because the myositis frequently involves the chest and upper abdomen. The enteroviral infection is known as *Bornholm disease*, named after the Danish island where it was first described.

Fungal infection (e.g., *Candida albicans*) can cause myositis. Candidal myositis is uncommon, however, and usually occurs in patients who are severely immunocompromised. Frequently, other sites also are involved by the disseminated fungal infection in addition to muscle.

Parasitic infection can cause myositis. The best known is trichinosis, caused by ingestion of the encysted larvae of *Trichinella spiralis*. The larvae typically are found in products containing pork or wild game, such as bear meat. The first signs of illness are fever and abdominal pain. Later, muscle pain is noted in the neck and chest. Eventually, calcifications form in the involved muscles. Treatment of the acute disease with mebendazole or albendazole may be beneficial. Another parasite more common in Central and South America is *Taenia solium*. Ingestion of eggs of this pork tapeworm leads to cysticercosis, with calcified densities in skeletal muscle. Finally, toxoplasmosis infection can lead to symptoms of myositis. During acute infection, *Toxoplasma gondii* can encyst in the skeletal muscle and lead to an inflammatory myopathy closely resembling dermatomyositis.

SECTION X

SKIN INFECTIONS

CHAPTER 58

Cutaneous Manifestations of Systemic Infections

James D. Cherry

Many illnesses caused by infectious agents have associated cutaneous manifestations. In some cases, the exanthem may be the hallmark of the disease; in others, it may be only a vague indicator of a more significant underlying process. When an exanthem occurs, it often offers important clues to the etiology of a patient's illness. Although most exanthematous illnesses in children are benign, their differential diagnosis is critical because the early manifestations of potentially fatal bacterial and rickettsial diseases frequently have cutaneous findings.

HISTORY

Exanthematous manifestations of infectious illnesses have been important since medical antiquity. Major epidemics of both measles and smallpox occurred in the Roman Empire and in China at the beginning of the Christian era.[26,139] Scarlet fever was recognized as a distinct entity in the 17th century, and chickenpox and rubella were identified in the 18th and 19th centuries, respectively.[50]

In the writings of the early 20th century, maculopapular exanthematous illnesses of children frequently were referred to by number. Scarlet fever and measles historically were the first two classic maculopapular exanthems of childhood. Which one had the honor of being the "first disease" is unknown today. The "third disease" was rubella, which was recognized by the beginning of the 20th century as a distinct entity.[73,92,169,175,194-196] In 1900, Dukes[73] described an exanthematous illness with the characteristics of both rubella and scarlet fever, which he suggested was a "fourth disease." The general opinion today is that his disease was not a distinct entity. Shaw[196] suggested that Dukes' cases had mild atypical scarlet fever, and Powell[169] raised the possibility that the illness resulted from epidermolytic toxin–producing staphylococci. My opinion has been (see first edition of this textbook) that probably rubella and scarlet fever both were epidemic in the student population under Dr. Dukes' care; combined infections led to the confusion. In 1991, Morens and Katz[147] came to the same conclusion.

Erythema infectiosum (see Chapter 151) commonly is referred to as the *fifth disease*, and roseola infantum (see Chapter 59) qualifies as the *sixth disease*.[195]

During the last 60 years, interest in exanthematous diseases has been renewed because a large number of previously unknown viruses and other infectious agents that cause cutaneous manifestations have been discovered. In addition, the pattern of disease caused by classic exanthem-producing agents has changed; smallpox has been eradicated, the epidemiology of measles and rubella has been altered by immunization, and ecologic changes have resulted in differences in viral and bacterially induced rashes.

ETIOLOGIC AGENTS

Many different types of viruses, chlamydiae, rickettsiae, mycoplasmas, bacteria, fungi, and protozoan and metazoan agents cause illnesses with associated cutaneous manifestations. Although this chapter is devoted to systemic infectious diseases with cutaneous manifestations, the demarcation between exanthematous disease of systemic and local origin is not always readily apparent. For example, the recurrent cold sore caused by herpes simplex virus (HSV) infection frequently is considered a local problem, although its nature and pathogenesis involve central virus latency and host systemic immune functions. Similarly, superficial fungal diseases and other local infections, such as warts, may be quite dependent on more general immunologic functions of the host. The exanthems of enteroviral infections frequently are confused with those caused by insect bites and allergic problems.

Table 58-1 presents viruses that have cutaneous manifestations in humans. Erythema infectiosum is caused by human parvovirus B19.[7,222] This virus also is an important cause of the papular-purpuric gloves and socks syndrome that is an uncommon occurrence and mainly affects young adults.* Human parvovirus B19 also has been associated with a vesiculopustular exanthem, erythema multiforme, and other petechial and purpuric rashes. In one study, an erythematous maculopapular rash was noted in 9 percent of children with human bocavirus infections.[10] Adenovirus types 1, 2, 3, 4, 7, and 7a have been isolated from children and young adults with exanthem.[50,116,226,227] The overall clinical expression rate of exanthem in adenovirus infection rarely has been studied. Fukumi and associates[85] noted that rash occurred in 2 percent of adenoviral infections, Hope-Simpson and Higgins[103] indicated a rate of approximately 8 percent, and Esposito and associates[75] noted an occurrence rate of 5.7 percent.

TABLE 58-1 **Clinical Characteristics of Viral Infections with Cutaneous Manifestations**

Virus	Disease or Syndrome	Incubation Period (days)	Main Season	Clinical Characteristics	Exanthem		Usual Duration (days)
					Lesions	Distribution	
Human parvovirus B19	Erythema infectiosum; gloves and socks syndrome	7-17	Winter and spring	Biphasic illness with mild prodromal period with headache and malaise for 2-3 days, then 7-day symptom-free period, followed by typical exanthema	Three-stage exanthema: Initially, rash on cheeks (slapped-cheek appearance) and then erythematous maculopapular rash on trunk and limbs; finally, rash develops a reticular pattern	Starts on face More prominent on extensor surfaces of extremities	7-21
Human bocavirus			Fall, winter, and spring	Fever, cough, coryza, respiratory distress (bronchitis, bronchiolitis, pneumonia)	Erythematous maculopapular	Mainly face, chest, and trunk	
Human papillomaviruses	Warts		Nonseasonal	Local cutaneous disease	Papular or nodular isolated lesions	Most common on extremities	100+
Adenovirus types 1, 2, 3, 4, 7, and 7a		6-9	Winter and spring	Fever and signs and symptoms of respiratory illness Occasionally, rash occurs after defervescence (roseola-like)	Most commonly erythematous, maculopapular, and discrete (rubelliform), but occasionally confluent (morbilliform) Rarely, erythema multiforme and Stevens-Johnson syndrome	Usually starts on face and spreads downward to trunk and extremities	3-5
Herpes simplex types 1 and 2	Cold sores, genital herpes, neonatal herpes, or other	2-12	Nonseasonal	Primary disease associated with fever and systemic symptoms Recurrent disease caused by exogenous and endogenous infections	Singular or grouped vesicular lesions varying in size from 2 to 10 mm, frequently on a mildly erythematous base Occasionally, erythema multiforme, Stevens-Johnson syndrome, and erythema nodosum	Lesions in primary infection with type 1 virus are mainly in and around the mouth Recurrent type 1 lesions usually perioral Primary and recurrent type 2 lesions usually on genitals	7-14
Human herpesvirus–6 (HHV-6)	Roseola infantum		Nonseasonal	Fever 3-5 days in duration, rapid defervescence, and then the appearance of rash	Erythematous macular or maculopapular	Most prominent on neck and trunk Face and extremities may be affected	1-2

Human herpesvirus–7 (HHV-7)	Roseola infantum		Nonseasonal	Fever 3-5 days in duration, rapid defervescence, and then the appearance of rash	Erythematous macular or maculopapular	Most prominent on neck and trunk Face and extremities may be affected	1-2
Human herpesvirus–8 (HHV-8)	Kaposi sarcoma	Months to years	Nonseasonal	Asymptomatic infection Most commonly noted in AIDS patients but occurs in other immunodeficiency states	Purple to blue nodular, raised lesions	Any epidermal or mucosal surface	Months to years
Varicella-zoster	Chickenpox (varicella)	12-20	Late fall, winter, and spring	Malaise and fever of 5-6 days duration	Basic lesion is vesicular, but lesions go through stages: macules, papules, vesicles, and crusts Lesions occur in crops	Lesions more profuse on trunk than on extremities Proximal end of extremities more involved than distal end	8-10
	Herpes zoster		Nonseasonal	Endogenous infection Pain and paresthesia with dermatome distribution	Basic lesion is vesicular, but lesions go through stages: macules, papules, vesicles, and crusts	Lesions localized to area of skin innervated by a single sensory ganglion	10-28
Epstein-Barr	Infectious mononucleosis	28-49	Nonseasonal	Fever, pharyngitis, and lymphadenopathy Exanthem occurs in 3%-13% of cases If ampicillin is administered, then exanthema in 50% of cases	Most commonly erythematous, macular, maculopapular, and discrete (rubelliform) In association with ampicillin administration, the rash may be more vivid Erythema multiforme and urticaria may occur	Mainly on trunk and proximal end of extremities	2-7
Cytomegalovirus	Cytomegalovirus mononucleosis		Nonseasonal	Acquired: mild febrile illness with lymphadenopathy Congenital: disseminated disease	Erythematous, maculopapular, and discrete Vesicular or petechial in congenital infection	Located mainly on trunk and proximal end of extremities	2-7

TABLE 58-1 **Clinical Characteristics of Viral Infections with Cutaneous Manifestations** (Continued)

Virus	Disease or Syndrome	Incubation Period (days)	Main Season	Clinical Characteristics	*Exanthem*		Usual Duration (days)
					Lesions	Distribution	
Vaccinia	Roseola vaccinatum, eczema vaccinatum, vaccination "take," or disseminated vaccinia		Nonseasonal	Illness caused by direct exposure via vaccination or exposure to a vaccinee	Vaccination and eczema vaccinatum lesions go through stages: papule, vesicle, pustule, and scab Roseola vaccinatum: erythematous maculopapular lesions Occasionally erythema multiforme Disseminated vaccinia: papular or vesicular lesions	Lesions in roseola vaccinatum, eczema vaccinatum, and disseminated vaccinia are generalized	7-14
Variola	Smallpox	8-17	Seasonal by geographic area	Abrupt onset of high fever, headache, and muscle and joint pain Rash appears 2-4 days after onset	Basic lesion is vesicular, but lesions go through stages: macules, papules, vesicles, pustules, and crusts	Most prominent on exposed body surfaces Starts on extremities and face Spreads centripetally	12-20
Monkeypox				Similar to mild smallpox Exposure to monkeys No human-to-human spread	Similar to mild smallpox	Similar to mild smallpox	
Orf	Ecthyma contagiosum	4-7	Spring	Disease of sheep acquired by humans	Initially erythematous papule Becomes umbilicated, nodular, and then vesicular Occasionally erythema multiforme	Solitary lesion, usually on hands	30-40
Molluscum contagiosum	Molluscum contagiosum			Local cutaneous disease	Umbilicated nodular lesions: singular or clusters	Most common on face, inner aspect of thigh, breasts, and genitalia	100+
Paravaccinia	Milker's nodules	4-7		Human infection acquired from infected calves	Nodular lesion Occasionally erythema multiforme	Solitary lesion, usually on hands	30-40
Tanapox				A virus of monkeys Human infection associated with fever and regional lymphadenopathy	Umbilicated vesicular lesion	Upper part of body Solitary lesion	35-56

Coxsackieviruses A2, A4, A5, A6, A7, A9, A10, and A16; coxsackieviruses B1-B5; echoviruses 1-7, 9, 11-14, 16-19, 24, 25, 30, and 33; enterovirus 71; parechoviruses 1 and 3		4-7	Summer and fall	Fever and mild to moderate pharyngitis Occasionally herpangina, meningitis, and other manifestations of systemic viral infection Exanthem occurs in 5%-50% of infections, depending on virus type Rash may occur during fever or after defervescence; hand, foot, and mouth syndrome	Most commonly erythematous, maculopapular, and discrete May have macular, petechial, vesicular, and urticarial components Rarely erythema multiforme	Usually starts on face and spreads downward to trunk and extremities May have peripheral distribution (hand, foot, and mouth syndrome)	3-7
Rhinoviruses (many types)		2-4	Fall, winter, and spring	Mild fever and signs and symptoms of respiratory illness Exanthem occurs in about 5% of cases	Erythematous or maculopapular and discrete	Starts on face and spreads downward to trunk and extremities	1-4
Foot and mouth		3-4		Direct animal contact Fever, sore mouth, and lymphadenopathy Vesicles and ulcers within the mouth	Vesicular lesions	Hands and feet	3-6
Colorado tick fever		3-5	Summer	Fever, chills, eye pain, myalgia, and headache Diphasic course Rash in only about 10% of cases	Occasionally maculopapular but usually petechial	Maculopapular rash is generalized Petechial rash most prominent on arms, legs, and trunk	2-7
Reovirus 2 and 3		4-7	Summer	Fever, mild pharyngitis, and cervical adenopathy	Erythematous or maculopapular Discrete or confluent Occasionally vesicular	Starts on face and spreads downward to trunk and extremities	3-9
Rotavirus	Gianotti-Crosti syndrome; infantile acute hemorrhagic edema	2-4	Fall, winter, and spring	Gastroenteritis	Petechial and morbilliform	Generalized	7-14

Continued on following page

TABLE 58-1 **Clinical Characteristics of Viral Infections with Cutaneous Manifestations** (Continued)

Virus	Disease or Syndrome	Incubation Period (days)	Main Season	Clinical Characteristics	*Exanthem*		Usual Duration (days)
					Lesions	Distribution	
Chikungunya, o'nyong-nyong, Ross River, Sindbis			During periods of arthropod prevalence	Fever, headache, eye pain, and marked myalgia, arthralgia, and arthritis Geographically localized diseases	Rubelliform and morbilliform Frequently vesicular and petechial	Starts on face and spreads downward to trunk and extremities	
Rubella	Rubella (German measles)	15-21	Winter and spring	Mild symptoms with onset 1-5 days before rash Fever usually <38.5° C (101.5° F) Headache, malaise, and suboccipital and postauricular lymphadenopathy	Erythematous, maculopapular, and discrete	Starts on face and spreads downward to trunk and extremities	4-7
West Nile				Sudden onset of fever, chills, and drowsiness Rash may appear during or after fever Geographically localized disease	Erythematous, macular, and maculopapular	Starts on trunk and spreads to extremities	3-6
Dengue and Kunjin		7	During periods of specific arthropod prevalence	Sudden onset of high fever, then severe headache, myalgia, arthralgia, abdominal pain, and marked diaphoresis Fever lasts 5-6 days and ends by crisis Rash appears within 48 hours of onset of fever Geographically localized diseases	Initially macular, flushed appearance, then erythematous, maculopapular rash May be scarlatiniform Frequently becomes petechial and purpuric Small vesicles occur in Kunjin virus infection	Initial macular rash is more prominent centrally Maculopapular rash may start on hands and feet and spread to trunk	3-10
Influenza A and B		2-5	Fall, winter, and spring	Fever, cough, headache, and muscle aches and pains Usually in young children Rash an occasional occurrence	Erythematous, maculopapular, and discrete (rubelliform) Rarely erythema multiforme	Starts on face and trunk and spreads to extremities	1-3

Respiratory syncytial		2-5	Fall, winter, and spring	Fever, coryza, and respiratory distress (bronchitis, bronchiolitis, or pneumonia) Usually in children <2 years	Erythematous, maculopapular, and discrete (rubelliform)	Starts on face and trunk and spreads to extremities	1-3
Human metapneumovirus			Fall, winter, and spring	Fever, coryza, and respiratory distress (bronchitis, bronchiolitis, or pneumonia)	Erythematous, maculopapular		
Parainfluenza 1-3		2-5	Fall, winter, and spring	Fever, coryza, nasopharyngitis, croup, and bronchitis Usually in young children	Erythematous, maculopapular, and discrete (rubelliform)	Starts on face and trunk and spreads to extremities	1-3
Mumps	Mumps	14-21	Fall, winter, and spring	Fever, headache, and salivary gland swelling	Erythematous, maculopapular, and discrete; also, urticaria and vesicles; rarely, erythema multiforme	Most prominent on trunk	2-5
Measles	Measles	8-12	Winter and spring	Onset with fever, cough, coryza, and conjunctivitis			
				About 2 days after onset, appearance of enanthem (Koplik spots); and 2 days later, onset of exanthem	Erythematous, maculopapular, and confluent Develops a brownish appearance, and fine desquamation occurs	Starts behind ears and on forehead Spreads downward over body Confluence most prominent on face, trunk, and proximal end of extremities	5-7
Lassa	Lassa fever			Sudden onset of fever, chills, headache, and sore throat Progresses to pneumonia and renal failure Geographically localized outbreaks	Macular and sometimes petechial	Localized or general

TABLE 58-1 **Clinical Characteristics of Viral Infections with Cutaneous Manifestations** (Continued)

Virus	Disease or Syndrome	Incubation Period (days)	Main Season	Clinical Characteristics	*Exanthem*		Usual Duration (days)
					Lesions	Distribution	
Hepatitis B	Papular acrodermatitis of childhood	50-180		Insidious onset with arthralgia, arthritis, and rash occurring before jaundice	Maculopapular, macular, or urticarial In young children, papular (Gianotti-Crosti syndrome or papular acrodermatitis of childhood) Rarely, erythema multiforme	Generalized	4-10
Hepatitis C	Mixed cryoglobulinemia (not reported in children)	7-14	Nonseasonal	Acute hepatitis followed by chronic infection Skin findings occur late in disease	Palpable purpura	Mostly buttocks, lower extremities	Variable
Marburg		5-7		Headache, conjunctivitis, photophobia, myalgia, vomiting, diarrhea, and fever (biphasic) Exposure to vervet monkeys	Initially erythematous macular, then discrete maculopapular, and finally confluent maculopapular Exfoliation occurs Occasionally purpura	Generalized	2-14
Ebola	Hemorrhagic fever	5-10	Occurs in outbreaks	Febrile illness that progresses to hemorrhage, shock, and coma	Maculopapular rash that appears toward end of first week of illness	Lateral sides of trunk, groin, and axillae Can become generalized but spares the face	14-60
Hantavirus	Hemorrhagic fever with renal syndrome (nephropathia epidemica)		Spring and summer outbreaks	Febrile illness with hemorrhagic and renal manifestations	Flushing and petechial rash	Face (flushing), skinfolds (petechiae)	14-28
HIV		14-60	Nonseasonal	Fever, pharyngitis, myalgia, arthralgias, adenopathy, and rash	Macular	Mainly chest and abdomen	7
Human T-lymphotropic virus	Infective dermatitis		Nonseasonal	Acute onset of eczema	Severe exudative eczema with a crusting, generalized, fine papular rash	Scalp, eyelid margins, perinasal skin, retroauricular areas, axillae, and groin	Months to years

Data from references 1, 2, 4, 6, 7, 9-13, 17, 20, 23, 27, 37, 40, 43, 45, 47, 49-51, 52, 59, 60, 62, 64, 65, 67, 80-85, 91, 96, 100, 102, 103, 106, 108, 110, 112, 118, 122, 123, 125, 128-130, 135, 145, 148-151, 154-156, 162, 164, 170, 178, 179, 181, 182, 184-186, 190, 191, 200, 201, 206, 209, 214, 215, 219, 222, 223, 225-227, 234-236.

Eight species in the *Herpesvirus* genus have cutaneous manifestations associated with infection, but clinical expression rates vary greatly. Nearly all primary varicella infections are associated with exanthem, whereas exanthem with acquired cytomegalovirus infection is a rare manifestation.* The incidence of exanthem in Epstein-Barr virus (EBV) infection varies from 3 percent to nearly 100 percent, depending on whether concomitant ampicillin is administered.† EBV has been associated with a unilateral laterothoracic exanthem in a 1-year-old girl and a drug-induced hypersensitivity syndrome in an 8-year-old boy.[71,188] Although firm data are lacking, probably fewer than 10 percent of primary infections with HSV type 1 are associated with cutaneous manifestations. Erythema multiforme occasionally occurs with recurrent HSV infections.[37,80,113,154] Human herpesvirus–6 (HHV-6) is a major cause of roseola infantum[12,222,235] (see Chapter 59). HHV-7 also is a cause of roseola infantum[11]; in addition, some evidence suggests that this virus and HHV-6 may play a role in pityriasis rosea.[68,69,174] HHV-8 infection is necessary for the development of Kaposi sarcoma in patients with acquired immunodeficiency syndrome (AIDS) and other immunodeficiency states.[108,122,145]

At present, human illnesses with cutaneous manifestations caused by poxviruses rarely occur in the United States. Because smallpox as a disease has ceased to exist, the use of vaccinia virus for immunization has decreased dramatically. However, the terrorist events of 2001 raised concern about the possible use of smallpox virus as a terrorist weapon. Because of this potential danger, smallpox vaccines are being produced and used again. With the increased use of these vaccines, cutaneous complications of vaccinia virus infection can be expected. Monkeypox is a relatively common illness in areas of Africa (see Chapter 163). Outside of Africa, monkeypox, orf, and paravaccinia (milker's nodules) continue to occur as isolated events in exposed individuals.[186,226,227] Human infection with tanapox virus is a geographically related illness occurring in limited areas of Kenya.

In the present era, enteroviruses are the leading cause of infection-related exanthematous diseases.[54,56,115,226,227] Thirty-eight types have been associated with rash illnesses. The clinical expression rate varies greatly among the different types; it is as high as 50 percent in children with coxsackievirus A16 and echovirus 9 infections. Only approximately 15 percent of individuals infected with echovirus 4 have exanthem, and rash is a rare occurrence in echovirus 6 infection. Hope-Simpson and Higgins[103] noted exanthem in approximately 5 percent of patients with rhinoviral respiratory illness.

A young adult research worker had an influenza-like illness and a hand, foot, and mouth syndrome–like rash caused by infection with a calicivirus (San Miguel sea lion virus serotype 5) of oceanic origin.[199]

Two percent of patients with Colorado tick fever encephalitis have exanthem.[54] Although infection with reoviruses occurs commonly, exanthem has been noted on only nine occasions.[54,129] A morbilliform rash has been observed in one adult with a rotavirus infection, and a 4-year-old boy was noted to have a petechial rash in association with a rotaviral illness.[62,182] Di Lernia and Ricci[64] described three cases of Gianotti-Crosti syndrome and one child with infantile acute hemorrhagic edema associated with rotavirus infections.

Of the *Togaviridae* family of viruses, rubella virus is the most important as a worldwide cause of exanthematous disease. Several alphaviruses also frequently cause exanthems.[114,151,226,227] Each of these viruses has a marked geographic distribution. Similarly, flaviviruses also have exanthem as part of their clinical expression, and they too have specific geographic boundaries.[226,227] In the New York City area outbreak of West Nile virus infection in 1999, 19 percent of patients had exanthem.[148] The rash was erythematous macular, papular, or morbilliform.

Exanthem generally is not considered to be a manifestation of influenza virus infection, but Hope-Simpson and Higgins[103] noted exanthem in approximately 8 percent of patients from whom influenza B virus was isolated and in 1 or 2 percent of those infected with influenza A virus. The occurrence of Gianotti-Crosti syndrome was noted 1 week after live H1N1 influenza virus vaccination in a 9 year-old boy.[121] Measles virus is the most notable of the *Paramyxoviridae* family with an associated exanthem. However, exanthem occurs rather frequently in young children infected with parainfluenza virus types 1, 2, and 3 and also in those with respiratory syncytial virus (RSV) illnesses.[86,97,99,216,219] Hope-Simpson and Higgins[103] noted a 15 percent incidence of rash in RSV infection and an approximately 15 percent incidence in parainfluenza virus infection. Rash, which was not described further, was observed in four children with respiratory illnesses caused by human metapneumovirus infections.[170] Exanthem also has been noted on rare occasion with mumps virus infection.[50]

An outbreak involving 185 cases caused by Zika virus (a flavivirus) occurred on an island in Micronesia in 2007.[72] The patients (children and adults) had fever, macular or maculopapular exanthems, arthritis or arthralgia, and nonpurulent conjunctivitis.

Lassa fever virus, Marburg virus, Ebola virus, and hepatitis B virus all have been associated with exanthem on occasion.* Rash was noted in 3/5 children with coronavirus OC43 lower respiratory tract infections.[210] Hepatitis B virus is the main cause of papular acrodermatitis (Gianotti-Crosti syndrome) in children.[47,185,191] Chronic hepatitis C virus infection occasionally causes systemic vasculitis and cryoglobulinemia in adults, with purpuric lesions concentrated on the lower extremities.[2,101] Other cutaneous manifestations of chronic hepatitis C virus infection include urticaria, erythema nodosum, lichen planus, and nodular prurigo.[112,234]

Hantaviruses cause two major syndromes throughout the world: hemorrhagic fever with renal syndrome and hantavirus pulmonary syndrome.[4,40,162,190] Exanthem (facial flushing and petechial lesions in skinfolds) occurs in approximately 30 percent of patients with hemorrhagic

†References 17, 29, 100, 110, 118, 158, 171, 214, 215.

*References 42, 46, 65, 79, 164, 226.

fever with renal syndrome, but rash is not reported in the hantavirus pulmonary syndrome. A macular rash has been noted in association with acute infection with human immunodeficiency virus type 1 (HIV-1).[8,148,150,205] Several reports have associated human T-lymphotropic virus type 1 (HTLV-1) with an atypical form of eczema termed *infective dermatitis*. This exanthem has an acute onset and is somewhat recalcitrant to treatment.[123,125,135]

Chlamydiae, rickettsiae, and mycoplasmas associated with cutaneous manifestations are listed in Table 58-2. Of the chlamydiae, only *Chlamydia psittaci* has been associated with exanthem. In contrast, all rickettsiae that infect humans, with the exception of *Coxiella burnetii*, usually display some cutaneous manifestations as part of their systemic disease.* Approximately 4 to 7 percent of adults with Q fever have exanthem.[40,203] Of the mycoplasmas that infect humans, only *Mycoplasma pneumoniae* is associated with exanthem.[14,53,54] In epidemics, exanthem occurs in approximately 15 percent of persons with respiratory illness.

In Table 58-3, bacterial agents for which cutaneous manifestations are part of the clinical illness are presented (see Chapter 60A). The clinical expression of exanthem varies tremendously among the different etiologic agents, as do the conditions associated with a specific infection. For example, infection with phage group 2 staphylococci usually results in cutaneous disease in young infants, whereas the same organisms rarely cause illness in adults. Symptomatic infection with *Streptococcus pneumoniae* is associated with cutaneous manifestations only occasionally; on the other hand, similar systemic disease with *Neisseria meningitidis* virtually always is associated with the characteristic petechial exanthem. Of the other bacterial agents listed in Table 58-3, exanthem is most important in *Neisseria gonorrhoeae*, *Salmonella typhi*, *Streptobacillus moniliformis*, *Spirillum minus*, *Pseudomonas aeruginosa*, and *Treponema pallidum*.

Fungal, protozoan, and metazoan agents associated with cutaneous manifestations in humans are listed in Tables 58-4, 58-5, and 58-6, respectively. These agents and their diseases, discussed more completely in other chapters, are included here for completeness of the differential diagnosis.

EPIDEMIOLOGY

Tables 58-1 through 58-6 clearly show that exanthematous disease has many possible etiologic agents; hence, no unified epidemiology exists. Epidemiologic events related to specific agents are considered in the appropriate sections throughout this text. Each agent with exanthem as a clinical manifestation has a unique epidemiologic pattern that, if understood, distinguishes it from many of the other agents that cause otherwise identical clinical illnesses. In the evaluation of all patients with rash, exposure, season, and incubation period are important aspects of the diagnostic process.

*References 32, 74, 90, 124, 131, 153, 159, 189.

PATHOPHYSIOLOGY AND PATHOLOGY OF EXANTHEMS

Even though the skin can respond in only a limited number of ways, what is obvious from the extensive number of etiologic agents is that multiple pathogenic mechanisms must occur. In many sections of this book, the pathology and pathophysiology of specific agents are presented in detail. An overview is presented here.

Small vessel vasculitis (leukocytoclastic vasculitis) is a leading event in most exanthematous illnesses caused by infectious agents.[202] The cutaneous manifestations of systemic diseases can be separated into three broad categories. The first category involves dissemination of infectious agents by blood (e.g., viremia and bacteremia), which results in secondary infection at the cutaneous site. The clinical cutaneous findings in this type of infection can be the direct result of infectious agents in the epidermis, dermis, or dermal capillary endothelium or can be the result of an immune response between the organism and antibody or cellular factors in the cutaneous location. The possible events in the skin with this type of infection are presented in Figure 58-1. Chickenpox, many enteroviral infections, and meningococcemia are examples of diseases in which infectious agents have reached the skin through the blood and are causing the cutaneous findings without the additional contribution of host immune factors. In illnesses such as measles, rubella, and gonococcemia, the timing, histologic picture, and difficulty of direct recovery of the agent by culture suggest both a direct effect and an immune-mediated response.

The second category of pathogenesis relates to the dissemination of known specific toxins of infectious agents. The infection is in a localized area of the body, but the toxin liberated by the infectious agents reaches the skin by blood-borne dissemination. Three examples of toxin-mediated exanthematous disease are streptococcal scarlet fever, staphylococcal scalded skin syndrome, and toxic shock syndrome.

The third category of pathogenesis in systemic disease with exanthem is poorly understood but appears to have an immunologic basis. Most important in this category are the clinical pictures of erythema multiforme, erythema multiforme exudativum (Stevens-Johnson syndrome), and erythema nodosum. In erythema multiforme associated with *M. pneumoniae* and HSV infection, the respective organisms have been isolated or identified at the skin site. In most instances, however, neither antigen localization nor disseminated toxin has been identified. The occurrence of erythema nodosum in a *Coccidioides immitis* infection indicates the development of cell-mediated immunity.

Important clinical aspects of exanthematous diseases are the distribution and progression of the lesions, yet little is known of the cause of these aspects. Differences in skin thickness, vascularity, proliferation rate, temperature, and metabolic activity are important in animal diseases with cutaneous manifestations.[54,77,133,144,166] In humans, similar factors must be important but obviously

TABLE 58-2 **Clinical Characteristics of Chlamydial, Rickettsial, and Mycoplasmal Infections with Cutaneous Manifestations**

					Exanthem		
Agent	**Disease or Syndrome**	**Incubation Period (days)**	**Main Season**	**Clinical Characteristics**	**Lesions**	**Distribution**	**Usual Duration (days)**
Chlamydia psittaci	Psittacosis	7-14	Nonseasonal	Fever, chills, headache, and cough Respiratory distress	Erythematous macules Occasionally erythema multiforme or erythema nodosum	Mainly on trunk	2-7
Rickettsia akari	Rickettsialpox	7-14	Nonseasonal	Fever, chills, headache, backache, and malaise 4-7 days after onset of primary lesion at site of mite bite Geographically localized disease	Initial lesion at site of mite bite is papular and then vesicular, and finally an eschar forms Two days after onset of fever, erythematous maculopapular discrete rash occurs Lesions progress to small vesicles and later to scabs	Most prominent on trunk and proximal end of extremities	7-10
Rickettsia typhi	Endemic, murine typhus	7-14	Nonseasonal	Fever and headache Rash appears on 4th-7th day Geographically localized disease	Initially discrete macules and then erythematous maculopapular May become purpuric	Initially upper part of trunk and axilla Progresses to entire body except face, palms, and soles	7-21
Rickettsia prowazekii	Epidemic typhus	10-14	Nonseasonal	Sudden onset of fever, chills, headache, and myalgias Rash appears on 4th-7th day Geographically localized disease	Initially discrete macules and then progresses to maculopapular and petechial lesions Sometimes purpuric	Appears first on trunk and spreads to extremities Spares palms and soles	7-14
Rickettsia tsutsugamushi	Scrub typhus	7-21	Nonseasonal	Sudden onset of chills, fever, and headache	Local lesion at site of chigger bite is present at onset of symptoms; characterized by vesicle, ulcer, and eschar Maculopapular rash occurs 5-8 days after onset of fever	Maculopapular rash first occurs on trunk and then becomes generalized	7-14
Rickettsia rickettsii	Rocky Mountain spotted fever	3-12	Summer	Abrupt onset of fever, chills, and headache Rash appears 2-4 days after onset	Early maculopapular, then petechial, and sometimes purpuric	Rash starts on distal end of extremities Rarely involves the trunk	7-14

TABLE 58-2 **Clinical Characteristics of Chlamydial, Rickettsial, and Mycoplasmal Infections with Cutaneous Manifestations** (Continued)

					Exanthem		
Agent	**Disease or Syndrome**	**Incubation Period (days)**	**Main Season**	**Clinical Characteristics**	**Lesions**	**Distribution**	**Usual Duration (days)**
Other tick-borne rickettsiae			Tick seasons	Similar to mild Rocky Mountain spotted fever	Similar to Rocky Mountain spotted fever; eschar at site of tick bite	Similar to Rocky Mountain spotted fever	7-14
R. sibirica	North Asian tick-borne rickettsiosis						
R. australis	Queensland tick typhus						
R. conorii	Boutonneuse fever; Mediterranean spotted fever						
R. africae	African tick fever						
Coxiella burnetii	Q fever	20-40	Nonseasonal	Acute febrile illness with chills, headache, and myalgia	Fine discrete macular rash occurring during febrile illness Transient urticarial rash also noted	Mainly on trunk	2-7
Ehrlichia and *Anaplasma* spp.	Ehrlichiosis; anaplasmosis	14-28	Tick seasons	Similar to Rocky Mountain spotted fever, but rash usually not on palms and soles	Similar to endemic typhus	Similar to endemic typhus	7-14
Mycoplasma pneumoniae		21	All seasons	Gradual onset of fever, malaise, headache, and cough	Maculopapular rash occurs in 5%-15% of cases Vesicular and bullous lesions common (Stevens-Johnson syndrome); more common in males Papular, petechial, and urticarial lesions also noted Erythema multiforme common	Rash most prominent on trunk and proximal end of extremities	7-14

Data from references 14, 15, 19, 32, 36, 41, 53, 54, 58, 74, 90, 97, 117, 124, 131, 138, 146, 153, 159, 172, 189, 205, 228, 233.

TABLE 58-3 **Bacteria Associated with Cutaneous Manifestations**

Agent	Disease or Syndrome	Clinical Characteristics	*Exanthem*	
			Lesions	**Distribution**
Gram-Positive Cocci				
Staphylococcus aureus, exfoliative toxin-producing, mainly phage group 2	Bullous impetigo	Usually occurs in neonates May be epidemic	Rapid progression from vesicles to bullous lesions	Most common in diaper area
	Scalded skin syndrome Toxic epidermal necrolysis (Ritter disease in infants <4 mo; Lyell syndrome in older children)	Usually occurs in infants and children 1 mo–5 yr of age Mucopurulent nasal and eye discharge Fever	Scarlatiniform eruption with exfoliation Nikolsky sign present Crusty appearance around eyes and under nose	Generalized Most marked on trunk
	Staphylococcal scarlet fever or staphylococcal scarlatiniform eruption	Fever and staphylococcal infection in throat, but no evidence of pharyngitis	Scarlet fever–like rash with desquamation Pastia lines present	Generalized
Staphylococcus aureus, nonexfoliative toxin-producing	Septicemic disease	Severe septicemia with osteomyelitis, arthritis, endocarditis, or pneumonia	Diffuse, erythematous, confluent, and macular rash (flush) With endocarditis, may have petechiae and splinter hemorrhages, Osler nodes, Janeway spots	Trunk and proximal end of extremities
Staphylococcus aureus, toxin-I (TSST-1)-producing	Toxic shock syndrome	Fever, intense myalgias, vomiting, and diarrhea Mental confusion and hypotension	Erythematous, deep red (sunburn-like) rash Desquamation occurs	Generalized
Staphylococcus aureus, nonexfoliative toxin-producing	Folliculitis, furuncles, or carbuncles	See primary skin infections, Chapter 60A		
Streptococcus pyogenes	Scarlet fever	Fever, pharyngitis, and cervical lymphadenitis Rash onset within 2 days of first symptoms Incubation period 3-4 days	Diffuse erythematous and fine maculopapular (looks and feels like red sandpaper) Rash darker in skinfolds (Pastia lines) Desquamation occurs	Circumoral pallor Generalized rash, with trunk and proximal end of extremities being most involved
	Erysipelas	Fever, headache, and vomiting Localized infection	Circumscribed area that is raised and erythematous Advancing edge is irregular	Anywhere
	Impetigo	Localized superficial pyoderma See primary skin infections, Chapter 60A	Discrete and coalescent lesions of a vesicular nature Quickly becomes more pustular and then crusts over with a yellowish-brown appearance	Forearms, legs, and face
	Septicemia	Fever and systemic foci of infection	Petechiae	Diffuse
	Miscellaneous skin manifestations of *S. pyogenes* infections		Erythema multiforme, erythema nodosum, and erythema marginatum	

Continued on following page

TABLE 58-3 **Bacteria Associated with Cutaneous Manifestations** (Continued)

			Exanthem	
Agent	**Disease or Syndrome**	**Clinical Characteristics**	**Lesions**	**Distribution**
Streptococcus pneumoniae	Septicemia	Fever	Petechiae	Diffuse
Enterococcal and viridans group streptococci	Endocarditis	Endocarditis	Petechiae, splinter hemorrhages, Osier nodes, and Janeway spots	
Gram-Negative Cocci				
Neisseria gonorrhoeae	Gonococcemia	Fever and polyarthralgias	Papular, petechial purpuric, pustular, or necrotic lesions	Most common on extremities Extensor surfaces over joints
Neisseria meningitidis	Meningococcemia	Fever and pharyngitis Sudden onset of rash	Characteristic rash is petechial or purpuric Early lesions may be erythematous maculopapular, or urticarial	Generalized
Moraxella catarrhalis	Bacteremia	Fever and pharyngitis	Maculopapular and petechial	Generalized
Gram-Positive Bacilli				
Bacillus anthracis	Anthrax	Fever, headache, malaise, and joint pain	Initially, macular, pruritic lesion Later, a papule forms and then vesiculation Vesicles last 2-6 days, and then eschar forms	Usually, single lesion initially at point of exposure, secondary lesions in area develop later
Listeria monocytogenes	Listeriosis	Neonatal meningitis with hepatosplenomegaly	Maculopapular, discrete lesions Pustules	Trunk and legs
Erysipelothrix rhusiopathiae	Crab or fishnet dermatitis	Fever and local pain	Erysipeloid lesion (violet or red)	Hands
Corynebacterium diptheriae	Cutaneous diphtheria	Secondary infection in cutaneous wounds	Impetigo or ecthyma-like Rarely, erythema multiforme	Exposed surfaces
Arcanobacterium hemolyticum	Scarlet fever–like illness	Fever and pharyngitis	Scarlet fever–like rash Occasionally, rubelliform	Generalized rash with peripheral predominance
Enteric Gram-Negative Bacilli				
Salmonella typhi	Typhoid fever	Malaise, headache, and marked fever Rash onset 10 days after onset of fever	Rose spots, 2- to 4-mm macular lesions	Discrete lesions on abdomen
Other *Salmonella* spp.	Septicemic salmonellosis	Similar to mild typhoid fever	Similar to typhoid fever	Similar to typhoid fever
Shigella sonnei	Shigellosis	Diarrhea	Urticaria	Diffuse
Campylobacter species		Gastroenteritis	Skin pustules and erythema nodosum	Lower part of legs
Other Gram-Negative Bacilli				
Francisella tularensis	Tularemia	Chills, fever, headache, and localized lymphadenopathy	Initial papule that later ulcerates	Site of inoculation
Haemophilus ducreyi	Chancroid	Local pain and tenderness	Pustular lesions that ulcerate	External genitalia
Haemophilus influenzae	Septicemia	Fever	Petechiae	Diffuse
			Reddish purple cellulitis	Cellulitis mainly on cheeks and extremities

Streptobacillus moniliformis	Rat-bite fever	Fever, chills, malaise, headache, and polyarthritis	Erythematous, maculopapular rash that may become petechial	Most prominent on extremities, including palms and soles
Yersinia pestis	Septicemic plague	Sudden onset of fever	Initial generalized erythema followed by petechiae and purpura	Generalized
Yersinia pseudotuberculosis		Mesenteric lymphadenitis	Erythema nodosum and scarlatiniform eruption	Lower part of legs and generalized
Yersinia enterocolitica	Yersiniosis	Enterocolitis	Erythema nodosum and urticaria	Lower part of legs and generalized
Bartonella bacilliformis	Bartonellosis, Carrión disease, or Oroya fever	Initially intermittent fever, malaise, and myalgias 30-60 days after initial fever, exanthem appears	Erythematous maculopapular Later recurrent nodules	Face and extensor surface of extremities
Bartonella quintana	Trench fever	Usually mild fever, headache, chills, and tibial bone pain	Macular rash	Mainly on trunk
Calymmatobacterium granulomatis	Granuloma inguinale	See *Calymmatobacterium granulomatis,* Chapter 130	Nodular, ulcerovegetative, hypertrophic, or cicatricial lesions	Genitals
Pseudomonas aeruginosa	Ecthyma gangrenosa	Septicemia (usually in immunocompromised patients)	Initially vesicular and then hemorrhagic Become ulcerated with central black necrotic eschar	Anywhere
	Pseudomonas folliculitis (health spa dermatitis)	Headache, malaise, and fatigue	Papular and pustular	Generalized
Burkholderia mallei	Glanders, melioidosis	Fever, malaise, chills, arthralgia, and muscle pains	Nodule or ulcer at site of inoculation and then widespread papules, bullae, and pustules	Generalized
Brucella spp.	Brucellosis	Acute or subacute febrile illness Erythematous and maculopapular	Exanthem in 8% of cases Occasionally vesicles	Generalized
Legionella pneumophila	Legionnaires disease	Severe pneumonia	Maculopapular	Anterior of trunk
Bartonella henselae	Cat-scratch fever	Subacute regional lymphadenitis	Erythematous maculopapular, morbilliform, petechial, erythema nodosum, erythema multiforme, and erythema marginatum May be pruritic	Generalized

TABLE 58-3 **Bacteria Associated with Cutaneous Manifestations** (Continued)

Agent	Disease or Syndrome	Clinical Characteristics	*Exanthem*	
			Lesions	**Distribution**
Acid-Fast Bacilli				
Mycobacterium tuberculosis	Lupus vulgaris	Usually associated with other manifestations of tuberculosis	Reddish-brown nodular or scaling lesions	Mainly on face and neck
	Papulonecrotic tuberculids	Associated with disseminated tuberculosis	Initially vesicular Become pustules, umbilical, and ulcerated and then form scabs and leave scars	Single or multiple lesions anywhere
Atypical mycobacteria			Granulomatous and ulcerative lesions at site of superficial injury	Usually on hands
Mycobacterium leprae	Erythema nodosum leprosum	General findings of lepromatous leprosy	Erythematous nodular lesions	Disseminated Most prominent on face and extremities
Spirochetes				
Treponema pallidum	Primary syphilis	Chancre	Large ulcers with indurated edges	Genitals
	Secondary syphilis		Erythematous maculopapules that frequently are scaly (psoriasiform)	Generalized, including palms and soles
Treponema pertenue	Yaws		Papular lesions at sites of inoculations Lesions ulcerate, leaving a wart-like appearance	Anywhere
Borrelia burgdorferi	Lyme disease (erythema chronicum migrans)	Skin, cardiac, neurologic, and joint abnormalities	Expanding erythematous, annular lesions	Thighs, buttocks, or axillae
Treponema carateum	Pinta		Initially, erythematous, papular lesions; increase in size during 1-month period and become scaly	Exposed surfaces of body
Spirillum minus	Rat-bite fever	Fever and chills	Discrete, macular rash	Trunk and extremities, including palms and soles
Leptospira spp.	Leptospirosis	Fever, conjunctivitis, and anorexia Rash rarely noted	Erythematous maculopapular rash	Mainly on trunk
Borrelia spp.	Relapsing fever	Relapsing fever, headache, myalgia, and photophobia	Morbilliform and petechial Erythema multiforme	Generalized

TABLE 58-4 Fungi Associated with Cutaneous Manifestations

			Exanthem	
Agent	**Disease or Syndrome**	**Clinical Characteristics**	**Lesions**	**Distribution**
Dermatophytic fungi	Tinea capitis, tinea cruris, tinea pedis, or tinea circinata		Localized, brownish, maculopapular lesions that are scaly	
Erythema nodosum				
Candida albicans	Congenital cutaneous candidiasis	Congenital infection	Discrete vesicular lesions	Generalized
	Chronic mucocutaneous candidiasis	Immunodeficiency disease	Confluent, erythematous, and exudative lesions	Generalized, including scalp
	Acquired candidiasis		Confluent, fiery red lesions	Most common in diaper area
Candida spp.	Systemic candidiasis	Severe opportunistic infection	Erythematous nodular lesions	Generalized
Histoplasma capsulatum	Histoplasmosis	Primary respiratory tract infection	Erythema nodosum, erythema multiforme, and erythematous maculopapular	
Cryptococcus neoformans	Cryptococcosis	Primary respiratory tract infection	Erythema nodosum and acneiform eruptions	
Coccidioides immitis	Coccidioidomycosis	Primary respiratory tract infection	Initially, erythematous, maculopapular rash Later, erythema multiforme and erythema nodosum	Generalized maculopapular rash
Sporotrichum schenckii	Sporotrichosis	Cutaneous inoculation	Nodular lesions that ulcerate	Usually hands, arms, and legs
Blastomyces dermatitidis	Blastomycosis	Primary respiratory tract infection	Nodular lesions that ulcerate Erythema nodosum	
Scedosporium spp.	No specific syndrome	Severe opportunistic infection	Nodular or necrotic skin lesions	Generalized
Fusarium spp.	No specific syndrome	Severe opportunistic infection	Nodular skin lesions, abscesses	Generalized
Aspergillus spp.	No specific syndrome	Severe opportunistic infection	Nodular and purpuric lesions	Generalized

TABLE 58-5 Cutaneous Manifestations of Protozoan and Helminthic Infections

Agent	**Disease or Syndrome**	**Cutaneous Manifestations**
Plasmodium spp.	Malaria	Occasionally generalized urticaria in chronic infection
Toxoplasma gondii	Acquired toxoplasmosis	Occasionally generalized erythematous, maculopapular rash
	Congenital toxoplasmosis	Generalized petechial rash
Giardia lamblia	Giardiasis	Rarely urticaria
Entamoeba histolytica	Amebiasis	Rarely urticaria
Leishmania tropica	Oriental sore	Red nodular lesion that ulcerates; lasts 2-3 mo
Leishmania braziliensis and *mexicana*	American cutaneous leishmaniasis	Erythematous papular lesion that vesiculates and ulcerates
Trypanosoma gambiense	African trypanosomiasis	Red nodular lesion at site of bite, followed by generalized, pruritic, erythema multiforme–like rash
Trypanosoma cruzi	American trypanosomiasis or Chagas disease	Nodular lesion at site of bite; generalized recurrent erythematous, maculopapular rash
Trichomonas vaginalis	Vulvovaginalis	Rarely urticaria and erythema multiforme
Ascaris lumbricoides	Roundworm infestation	Erythema nodosum
Enterobius vermicularis	Pinworm infestation	Rarely urticaria
Necator americanus	Hookworm disease	Papules and papulovesicles on exposed surfaces (feet); generalized urticaria

Continued on following page

TABLE 58-5 **Cutaneous Manifestations of Protozoan and Helminthic Infections** (Continued)

Agent	Disease or Syndrome	Cutaneous Manifestations
Trichinella spiralis	Trichinosis	Urticaria common; also, generalized maculopapular rash may occur; petechiae frequently develop
Strongyloides stercoralis	Strongyloidiasis; also, creeping eruption (cutaneous larva migrans)	Erythematous, maculopapular lesions on feet; creeping eruption
Ancylostoma braziliense	Creeping eruption (cutaneous larva migrans)	Creeping eruption
Dermatobia hominis	Cutaneous myiasis	Creeping eruption, subacute draining lesions
Schistosoma haematobium, mansoni, and *japonicum*	Schistosomiasis	Pruritic papular eruption where exposed; generalized urticaria and granulomatous lesions
Trichobilharzia ocellata, physellae, and *stagnicolae*	Swimmer's itch or collector's itch	Initial erythema and urticaria followed by papules and vesiculation; pruritic
Wuchereria bancrofti	Filariasis	Localized erythema urticaria and erythema nodosum
Onchocerca volvulus	Onchocerciasis	Chronic, papular, scaly rash
Echinococcus granulosus and *multilocularis*	Echinococcosis	Frequent urticaria

Data from references 15, 21, 43, 57, 74, 76, 89, 94, 143.

TABLE 58-6 **Cutaneous Manifestations of Arthropod Bites and Stings**

Agent	Disease or Syndrome	Cutaneous Manifestations
Spiders		
Loxosceles rectus	Recluse spider bite or brown spider bite	Erythema followed by blister and necrosis
Ticks	Tick bite	Initial pruritus at site; becomes ulcerated and granulomatous
Mites		
Sarcoptes scabiei	Scabies	Pruritic burrows in body creases and generalized; become erythematous and then papular urticaria
Trombicula irritans	Chigger bite	Marked pruritus and then papular urticaria
Other mites: Food, grain, murine, and fowl		Marked pruritus and then papular urticaria
Lice		
Pediculus humanus	Body lice or pediculosis	Erythematous, maculopapular, pruritic lesions; sometimes urticaria
Phthirus pubis	Crabs	Pruritus and erythema under pubic hair
Bedbugs and kissing bugs		
Cimex lectularius	Bedbug bite	Pruritic papular urticaria
Triatoma sanguisuga	Kissing bug bite	Papular urticaria; occasionally hemorrhagic nodular lesions
Gypsy moth caterpillar		
Lymantria dispar	Gypsy moth rash	Pruritic blotchy erythema and maculopapular
Moths		
Hylesia alinda	Moth-associated dermatitis	Erythema and pruritus; feeling of warmth in area of rash; may have vesicular lesions
Ants		
Solenopsis saevissima	Fire ant bite	Painful papular urticarial lesions that become pustular and then nodular
Fleas		
Pulex irritans (human flea) and fleas of many animals	Flea bite	Papular urticaria
Flies and mosquitoes	Fly and mosquito bite	Papular, nodular, and urticarial lesions in sensitive persons

Data from references 46, 48, 63, 74, 101, 160, 180, 192, 197.

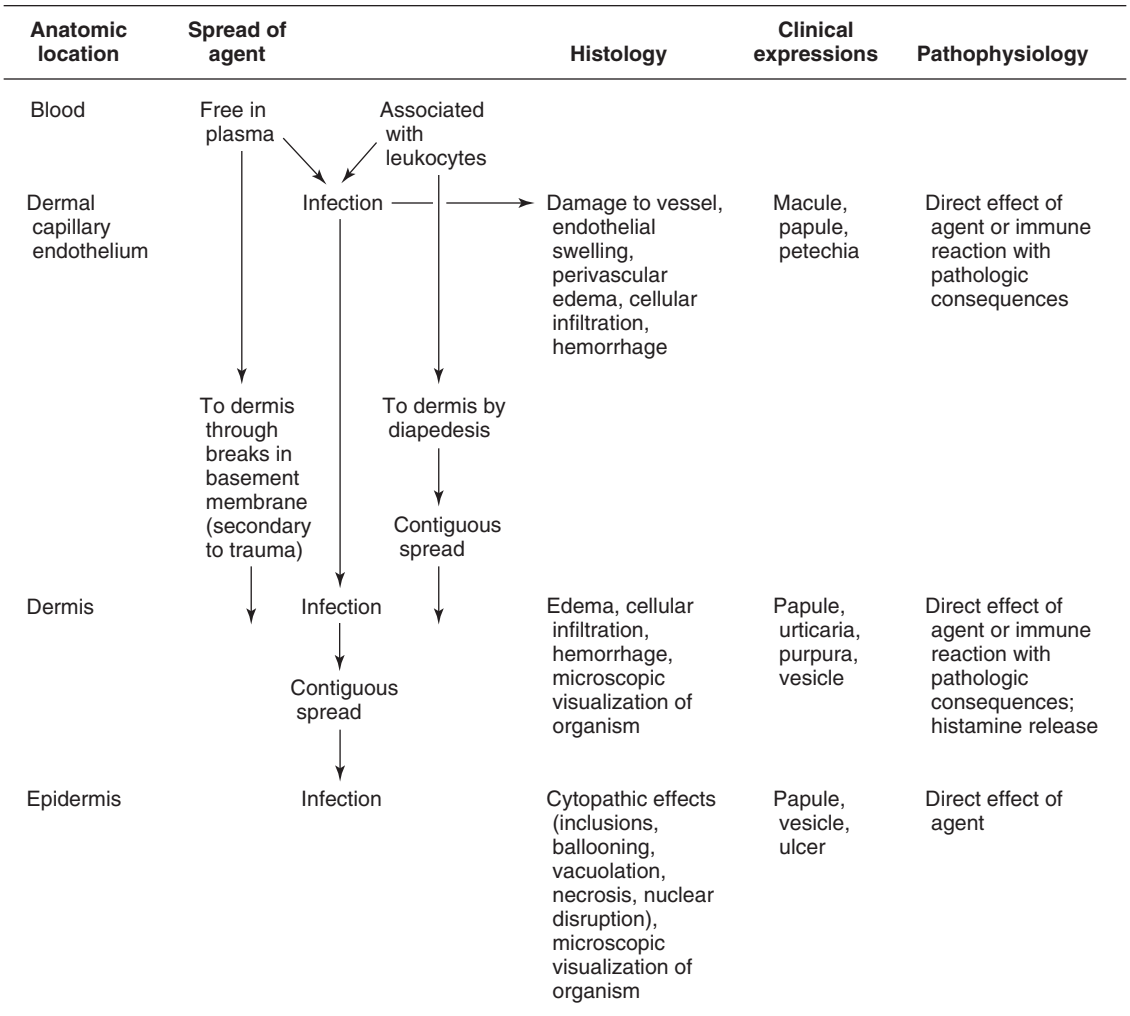

FIGURE 58-1 ■ Aspects of pathogenesis in exanthems associated with blood-borne dissemination of the infectious agent. (Modified from Cherry JD. Newer viral exanthems. Adv Pediatr 1969;**16**:233-86.)

affect the various etiologic agents differently (e.g., the more central exanthem of chickenpox vs. that of the hand, foot, and mouth syndrome of coxsackievirus A16 infection).

CLINICAL MANIFESTATIONS

The clinical findings in exanthematous diseases resulting from systemic infections are varied and depend on the inciting pathogens. By examination of skin alone, differentiating an exanthematous disease resulting from systemic infection (e.g., coxsackievirus A9, rubella virus infection) from primary cutaneous diseases of infectious and noninfectious origin (e.g., insect bites, acne, and contact with poison ivy) frequently is difficult. In Tables 58-1 through 58-6, the clinical characteristics of viral, chlamydial, rickettsial, bacterial, fungal, parasitic, and arthropod-induced illnesses with primary or secondary cutaneous manifestations are presented. In Tables 58-8 through 58-17, etiologic agents and clinical manifestations are presented on the basis of the more pronounced cutaneous manifestations or syndrome associations. The clinician must keep in mind that other aspects of an illness (e.g., exposure, season, incubation period, geographic location, patient age, and associated signs and symptoms) may be more important in determining the underlying etiologic agent. Clinical manifestations of specific exanthematous diseases are presented in greater detail in other chapters of this book.

Erythematous Macular Exanthems

When all infectious diseases with exanthems are taken into consideration, the occurrence of illnesses in which the lesions are just macular is rare. However, many important, severe diseases have a transitory erythematous macular rash early in their course, and recognition of this fact can be lifesaving. Infectious agents associated with illnesses in which macular exanthems have been observed are presented in Table 58-7.

TABLE 58-7 **Infectious Agents Associated with Illness in Which a Macular Exanthem Has Been Observed**

Infectious Agent	Illness
Human herpesvirus–6, 7	Roseola infantum
Epstein-Barr virus	Infectious mononucleosis
Coxsackieviruses BI, B2, B5	—
Echoviruses 2, 4, 5, 14, 17-19, 30	—
Enterovirus 71	—
Dengue virus	Dengue fever
Lassa virus	Lassa fever
Marburg virus	Marburg fever
Parvovirus	Erythema infectiosum
HIV-1	Manifestation of acute infection
Hantavirus	Hemorrhagic fever with renal syndrome
Chlamydia psittaci	Psittacosis
Rickettsia typhi	Murine typhus
Rickettsia prowazekii	Epidemic typhus
Rickettsia quintana	Trench fever
Coxiella burnetii	Q fever
Mycoplasma pneumoniae	—
Staphylococcus aureus	Septicemia and toxic shock syndrome
Streptococcus pyogenes	Scarlatina and septicemia
Bacillus anthracis	Anthrax
Salmonella typhi	Typhoid fever
Salmonella spp.	Septicemic salmonellosis
Spirillum minus	Rat-bite fever
Leptospira spp.	Leptospirosis
Yersinia pestis	Plague

The most common rash in infectious mononucleosis is erythematous and maculopapular, but rarely (most often in association with the administration of ampicillin) the exanthem is generalized, confluent, fiery red, and macular. Blotchy or diffuse erythematous macular rashes have been caused specifically by 12 different enterovirus types. Most of these descriptions involve neonates, other very young infants, and adults; children in the peak ages for enteroviral exanthematous diseases do not seem to have solely macular lesions. In neonates, enteroviral disease with a blotchy macular rash in association with fever and lethargy usually is confused with bacterial sepsis.

Patients with dengue, Lassa, and Marburg viral infections frequently have a macular, flushed appearance before other cutaneous manifestations develop. Similarly, in both murine and epidemic typhus, the initial skin manifestations are macular but progress rapidly to more pronounced findings.

Bacterial septicemia with both common and exotic organisms is associated frequently with a generalized flush. In staphylococcal disease, the rash is particularly apparent in endocarditis and osteomyelitis. The most famous disease with a macular rash is typhoid fever. Rose spots occur most commonly on the abdomen, but they also are seen on the chest and back. They are 2- to 4-mm erythematous, macular lesions. Lesions likewise have been noted in leptospirosis and psittacosis. In addition, rose spots are seen occasionally in septicemic illnesses caused by other *Salmonella* spp.

The slapped-cheek appearance in erythema infectiosum is caused by an erythematous macular flush of the cheeks. The full-blown rash in streptococcal scarlet fever is maculopapular, but frequently in mild cases and in those altered by antibiotic therapy, the exanthem is only macular (scarlatina).

Erythematous Maculopapular Exanthems

An erythematous maculopapular rash is the most common cutaneous manifestation of systemic infection. It also is an exceedingly common occurrence in allergic conditions. However, all too frequently, the rash of an infectious illness is ascribed to an allergic reaction to an administered drug rather than correctly to the disease process. The converse—an allergic rash illness attributed mistakenly to an infectious agent—rarely occurs. Infectious agents associated with illnesses in which maculopapular exanthems occur are presented in Table 58-8.

Both by the number of possible etiologic agents and by total infections, viruses account for the vast majority of illnesses with maculopapular eruptions. Although the distribution and progression of rashes are important aspects relating to the differential diagnosis, the single most important point is whether the lesions are discrete (rubelliform) or confluent (morbilliform). Adenoviruses are not uncommon causes of erythematous maculopapular eruptions. In most instances, signs and symptoms of upper respiratory tract infection are present. Most commonly, the lesions are discrete, but occasionally, a confluent morbilliform rash is present. A roseola infantum picture—occurrence of rash after the fever falls by crisis—frequently occurs. As a rule, the exanthem in adenoviral infections starts on the head and spreads to the trunk and extremities.

Enteroviruses account for the greatest number of erythematous maculopapular rash illnesses; 37 different serologic types have been implicated. The enteroviral types most commonly associated with maculopapular exanthems are coxsackieviruses A9 and B5 and echoviruses 4, 9, and 16. Echovirus 9 has been the most frequent cause of enteroviral exanthem for the last 35 years. Although morbilliform rashes do occur, the more usual cutaneous manifestation is one suggestive of rubella. The exanthem usually starts on the head and upper part of the trunk and spreads to the extremities.

Although they are not common manifestations of respiratory viruses (e.g., rhinoviruses, influenza A and B viruses, RSV, and parainfluenza viruses types 1 through 4), exanthems probably occur more often than is generally realized. Because children infected with these agents frequently are given antibiotics, confusion often occurs between an allergic and an infectious etiology. With all the respiratory viruses, the signs and symptoms of

respiratory illness (e.g., cough, coryza, croup, and bronchiolitis) are prominent. The exanthems virtually are always discrete and rubelliform.

In dengue, the exanthem goes through several stages. Initially, it is macular, then erythematous maculopapular, and finally hemorrhagic. Similarly, the exanthems in the rickettsial diseases go through stages that vary in relation to the specific agent (see Table 58-2). In Rocky Mountain spotted fever, the rash starts on the distal ends of extremities. Although the hallmark of meningococcemia is a petechial or purpuric rash, in the initial stages, the exanthem may be erythematous and maculopapular. In addition, maculopapular eruptions are observed in chronic meningococcemia. The most notable cutaneous lesion in coccidioidomycosis is erythema nodosum, but a rubelliform rash early in infection is not an unusual manifestation.

Vesicular Exanthems

The three main categories of vesicular exanthems are single or localized lesions, generalized lesions in greatest concentration on the trunk and head, and generalized lesions with the greatest concentration on the extremities. Infectious agents associated with illnesses in which vesicular rashes develop are presented in Table 58-9. The exanthem in primary or recurrent HSV infection is localized, as it is in recurrent endogenous varicella-zoster infection (herpes zoster), ecthyma contagiosum, tanapox, scrub typhus, anthrax, and papulonecrotic tuberculids.

The vesicular exanthematous disease that occurs most commonly in children today is chickenpox. It should be a readily recognizable disease, but is all too frequently confused with enteroviral infections or insect bites and allergic conditions. Chickenpox has a long incubation period (16 days) and is associated with mild fever and an exanthem that starts on the head and upper part of the trunk and spreads to the extremities. The rash always is more prominent on the trunk than on the extremities. At any time during the first few days of the rash, lesions in all stages (i.e., macules, papules, and vesicles) can be seen. Individual lesions in chickenpox form scabs that persist for approximately 7 days.

In contrast to that of chickenpox, the exanthem in enteroviral infections frequently is peripheral in distribution, and the lesions generally heal without scabs. The incubation period (5 days) is much shorter than that of chickenpox. The hand, foot, and mouth syndrome is a common manifestation of enteroviral vesicular rash illnesses. Until relatively recently, the most frequent etiologic agent in the hand, foot, and mouth syndrome was coxsackievirus A16, but the syndrome also had been attributed to coxsackieviruses A5, A9, A10, B1, and B3 and enterovirus 71. In recent years, enterovirus 71 is the most common cause of this syndrome. Most recently coxsackievirus A6 has been noted in several outbreaks.[155,223]

Enteroviral infections with vesicular exanthems in which the hand, foot, and mouth distribution is not present quite frequently are diagnosed erroneously as insect bites or poison ivy.

TABLE 58-9 **Infectious Agents Associated with Illnesses in Which Vesicular Exanthems Occur**

Infectious Agent	Illness
Human parvovirus B19	
Herpes simplex virus types 1 and 2	Cold sores, genital herpes, or neonatal herpes
Varicella-zoster virus	Chickenpox (varicella) or herpes zoster
Vaccinia virus	Disseminated vaccinia or eczema vaccinatum
Variola virus	Smallpox
Monkeypox virus	
Orf virus	Ecthyma contagiosum
Tanapox virus	
Coxsackieviruses A4, A5, A6, A8, A10, A16	
Coxsackieviruses BI-B3	
Echoviruses 6, 9,11, 17	
Enterovirus 71	
Reovirus 2	
Calicivirus of oceanic origin	
Alphaviruses: Chikungunya, o'nyong-nyong fever, Ross River, Sindbis	
Kunjin virus	
Mumps virus	Mumps
Measles virus	Atypical measles
Rickettsia akari	Rickettsialpox
Rickettsia tsutsugamushi	
Mycoplasma pneumoniae	
Streptococcus pyogenes	Impetigo
Pseudomonas aeruginosa	
Brucella spp.	Brucellosis
Bacillus anthracis	Anthrax
Mycobacterium tuberculosis	Papulonecrotic tuberculids
Candida albicans	Congenital cutaneous candidiasis
Leishmania braziliensis	American cutaneous leishmaniasis
Necator americanus	Hookworm disease

Petechial and Purpuric Exanthems

A large number of infectious agents are associated with petechial and purpuric skin manifestations and are listed in Table 58-10. Infectious diseases with hemorrhagic rash can be fulminant fatal events or relatively benign illnesses. On a worldwide basis, meningococcemia is perhaps the most important and feared, although it is not the most prevalent of the petechial and purpuric exanthematous diseases. The relatively sudden onset of fever and a petechial rash must be considered and treated as meningococcemia unless another etiology can be established with absolute certainty. The most important of the differential diagnostic problems is exanthem caused by enteroviral infection. Many different enterovirus illnesses have a sudden onset with accompanying fever and petechial rash. In addition, the situation frequently is

TABLE 58-10 **Infectious Agents Associated with Illness in Which Petechial and Purpuric Exanthems Occur**

Infectious Agent	Illness
Human parvovirus B19	Glove and socks syndrome
Varicella-zoster virus	Hemorrhagic chickenpox
Cytomegalovirus	Congenital cytomegalovirus infection
Variola virus	Hemorrhagic smallpox
Coxsackieviruses A4, A9	
Coxsackieviruses B2-B4	
Echoviruses 4, 7, 9	
Colorado tick fever virus	Colorado tick fever
Rotavirus	
Alphaviruses: Chikungunya, o'nyong-nyong fever, Ross River, Sindbis	
Rubella virus	Rubella (German measles) or congenital rubella
Respiratory syncytial virus	
Measles virus	Hemorrhagic (black measles) or atypical measles
Lassa virus	Lassa fever
Marburg virus	
Hepatitis C virus	Mixed cryoglobulinemia
Hantavirus	Hemorrhagic fever with renal syndrome
Rickettsia typhi	Murine typhus
Rickettsia prowazekii	Epidemic typhus
Rickettsia rickettsii and other tick-borne rickettsiae	Rocky Mountain spotted fever
Ehrlichia species	Ehrlichiosis
Mycoplasma pneumoniae	
Streptococcus pyogenes	Scarlet fever or septicemia
Streptococcus pneumoniae	Pneumococcal septicemia
Enterococcal and viridans group streptococci	Endocarditis
Neisseria gonorrhoeae	Gonococcemia
Neisseria meningitidis	Meningococcemia
Moraxella catarrhalis	
Haemophilus influenzae	*H. influenzae* septicemia
Pseudomonas aeruginosa	Ecthyma gangrenosa
Streptobacillus moniliformis	
Yersinia pestis	Septicemic plague (black death)
Bartonella henselae	Cat-scratch fever
Treponema pallidum	Congenital syphilis
Borrelia species	Relapsing fever
Toxoplasma gondii	Congenital toxoplasmosis
Trichinella spiralis	Trichinosis

Pediculus humanus	Pediculosis
Bedbugs, kissing bugs, ants, fleas, flies, and mosquitoes	Bites and stings

complicated further by the occurrence of meningitis. The most important enterovirus in its ability to mimic meningococcemia is echovirus 9.

Purpuric and petechial lesions in infectious illnesses can result from a direct or indirect (immunologic) effect of the infectious agent at the cutaneous site or from the occurrence of thrombocytopenia. Thrombocytopenia is noted most commonly in acquired rubella virus infections.

Urticarial Exanthems

The occurrence of urticaria all too frequently leads the physician to suspect an allergic or dermatologic condition.[216,217] However, what has become quite evident is that when urticaria develops in association with an acute febrile illness, the cutaneous reaction is a direct effect of an infectious agent and its mediation does not require an allergic response. Listed in Table 58-11 are infectious agents associated with urticarial exanthems.

Papular urticaria occurs very commonly in children in the summer and fall and most frequently is the result of insect bites (see Table 58-6). However, virtually identical lesions occur in infections with coxsackievirus A as well as with other enteroviruses. The main point for differentiation is that fever regularly develops in the virus-induced exanthems but is not a characteristic associated with insect bites.

Early in the course of meningococcemia, the exanthem can be urticarial, so an illness of sudden onset with

N, Nodular; *P,* papular; *U,* ulcerative.

fever and this cutaneous manifestation never should be taken lightly.

Papular, Nodular, and Ulcerative Lesions

In many instances, the lesions in this category occur as single events at the site of primary inoculation. Specific illnesses and etiologic agents are listed in Table 58-12.

Distinctive Clinical Features or Syndromes

Erythema Multiforme

Erythema multiforme is a self-limited skin eruption that is erythematous and characterized by distinctive target or iris lesions or both. Small vesicles and urticarial areas also may develop. On occasion, the disease is severe and associated with mucosal involvement and genital lesions. In this latter illness—the Stevens-Johnson syndrome, bullous erythema multiforme, erythema multiforme exudativum major—severe ulcerative, oral, and genital lesions occur; generalized exanthems become bullous, and conjunctivitis is present. The illness is associated with fever and general distress.

Although the pathogenesis of erythema multiforme is unknown, what is clear is that multiple factors, including infectious agents, are responsible for its occurrence. Infectious agents associated with erythema multiforme are listed in Table 58-13. The single most important infectious cause of erythema multiforme and Stevens-Johnson syndrome is *M. pneumoniae*. When *M. pneumoniae* is the instigating agent, the patient nearly always has concomitant pneumonia.

HSV frequently has been recovered from the throats of persons with erythema multiforme, but the cause-and-effect relationship in many cases must be questioned. However, in a recent study, HSV DNA was found in the skin lesions of 11/31 patients with erythema multiforme.[60]

Erythema Nodosum

Erythema nodosum most commonly occurs on the anterior aspect of the lower part of the legs but may be seen anywhere on the body. The lesions are raised, erythematous, and painful to touch. Their usual size is approximately 2 to 4 cm, with a duration of 2 to 6 weeks.

Erythema nodosum occurs less commonly today than it did 4 decades ago, and the frequency of specific associated infectious agents also is different. In the past, streptococcal and mycobacterial infections were the agents most commonly related. Now, the exanthem most often is associated with respiratory tract infection with *Histoplasma capsulatum*, *Cryptococcus neoformans*, and *C. immitis*. Infectious agents associated with erythema nodosum are listed in Table 58-14.

Hand, Foot, and Mouth Syndrome

The hand, foot, and mouth syndrome is a clearly recognizable viral illness characterized by vesicular lesions in the anterior of the mouth and on the hands and feet in association with fever. Although several enteroviruses (i.e., coxsackieviruses A5, A6, A9, A10, A16, B1, and B3 and enterovirus 71) have been implicated, as have HSV and foot and mouth disease virus, most of these cases today are caused by enterovirus 71 and perhaps coxsackievirus A6.

TABLE 58-13 **Infectious Agents Associated with Erythema Multiforme**

Agent	Illness
Human parvovirus B19	Erythema infectiosum
Adenovirus 7	Respiratory tract infection
Herpes simplex virus type 1	Perioral or respiratory tract infection
Epstein-Barr virus	Infectious mononucleosis
Varicella virus	Chickenpox
Coxsackieviruses A10, A16, B5	Enterovirus syndrome
Echovirus 6	Enterovirus syndrome
Poliomyelitis virus	Poliomyelitis
Vaccinia virus	Smallpox vaccination

Coccidioides immitis	Coccidioidomycosis
Blastomyces dermatitidis	Blastomycosis
Ascaris lumbricoides	Roundworm infestation
Wuchereria bancrofti	Filariasis

Roseola-like Illness

Roseola infantum is a classic pediatric illness characterized by fever of 3 to 5 days' duration, rapid defervescence, and then the appearance of an erythematous macular or maculopapular rash that persists for 1 to 2 days. Roseola is an age-related response to infection with many viruses. Recent studies suggest that a leading cause of roseola infantum is primary infection with HHV-6. The following other viruses have been noted in association with roseola: adenoviruses 1, 2, 3, and 14; coxsackieviruses A6, A9, B1, B2, B4, and B5; echoviruses 9, 11, 16, 25, 27, and 30; parainfluenza virus type 1; and measles vaccine virus.

Rocky Mountain Spotted Fever–Like Illness

Rocky Mountain spotted fever is a clinical illness characterized by fever and a petechial rash located mainly on the distal ends of extremities. The illness is caused by *Rickettsia rickettsii* and is prevalent in many areas of North America; the infectious agent is transmitted to humans by ticks. In other areas of the world, other tick-borne rickettsiae *(Rickettsia sibirica*, *Rickettsia australis*, *Rickettsia conorii)* produce similar human illness. Infection with *Ehrlichia* spp. also can cause an illness similar to Rocky Mountain spotted fever.

The most important illness that, in the past, was confused with Rocky Mountain spotted fever was atypical measles (see Chapter 179). This illness, which has both the constitutional symptoms of Rocky Mountain spotted fever and a rash most prominent on the extremities, occurs almost exclusively after exposure to measles virus in some persons previously immunized with inactivated (killed) measles vaccine.

Rat-bite fever caused by *S. moniliformis* also has been misdiagnosed as Rocky Mountain spotted fever.[168]

Exanthem and Meningitis

Aseptic and also bacterial meningitis frequently are characterized by both exanthem and symptoms and signs of neurologic involvement. Infectious agents associated with exanthem and meningitis are presented in Table 58-15. Of most importance in this category is the differential diagnosis of enteroviral syndromes and meningococcemia.

TABLE 58-15 **Infectious Agents Associated with Exanthem and Meningitis**

Agent	Illness
Herpes simplex virus type 2	Recurrent genital herpes
Coxsackieviruses A2, A9, B1, B4, B5	Enterovirus syndrome
Echoviruses 4, 6, 9, 11, 14, 17, 25, 33	Enterovirus syndrome
Colorado tick fever virus	Colorado tick fever
Reovirus 2	Respiratory tract infection
West Nile virus	Meningoencephalitis
Neisseria meningitidis	Meningococcemia
Borrelia burgdorferi	Lyme disease
Listeria monocytogenes	Listeriosis
Toxoplasma gondii	Toxoplasmosis

TABLE 58-16 **Infectious Agents Associated with Exanthem and Pulmonary Involvement**

Agent	Illness
Adenoviruses 7,7a	Respiratory tract infection
Herpes simplex virus type 1	Respiratory tract infection
Varicella-zoster virus	Chickenpox pneumonia
Epstein-Barr virus	Infectious mononucleosis
Coxsackievirus A9	Enterovirus syndrome
Echovirus 11	Enterovirus syndrome
Reovirus 3	Respiratory tract infection
Measles virus	Measles pneumonia and atypical measles
Chlamydia psittaci	Psittacosis
Mycoplasma pneumoniae	*M. pneumoniae* pneumonia
Neisseria meningitidis	Meningococcal pneumonia
Mycobacterium tuberculosis	Tuberculosis
Histoplasma capsulatum	Histoplasmosis
Cryptococcus neoformans	Cryptococcosis
Coccidioides immitis	Coccidioidomycosis

Exanthem and Pulmonary Involvement

Infectious agents associated with exanthem and pulmonary involvement are listed in Table 58-16. In patients older than 5 years of age, the leading cause of exanthem and pneumonia is *M. pneumoniae* infection. In younger children, adenoviruses are the most important etiologic agents. With the exception of enteroviral infections, which are more likely to involve young children, most of the illnesses listed in Table 58-16 occur in older children and young adults.

Gianotti-Crosti Syndrome (Papular Acrodermatitis)

Gianotti-Crosti syndrome is a distinct clinical entity characterized by a papular (lichenoid) exanthem, generalized lymphadenopathy, hepatomegaly, and acute anicteric hepatitis.[47,186,189] In most instances, this illness has been associated with hepatitis B virus infection. The syndrome also has been noted in association with EBV, cytomegalovirus, coxsackievirus B virus, and RSV infections.[66,118,187,209]

Cutaneous Manifestations Associated with Infections in Immunocompromised Patients

All infectious agents that cause exanthems in immunologically normal children can cause infections in immunocompromised children. However, the clinical manifestations may be different. For example, measles virus infection in a child who is T-cell–deficient may be associated with a severe, progressive pneumonia but not the typical rash. Other viral exanthems that are self-limited in normal children, such as varicella, may be progressive and develop into hemorrhagic skin lesions with disseminated organ involvement in children with T-cell deficiency.

Of particular concern are bacterial and fungal infections, which are rarely a problem in normal children but are rapidly fatal in granulocytopenic children. These patients have characteristic skin lesions resulting from disseminated infections. Of importance are ecthyma gangrenosa resulting from *P. aeruginosa* septicemia and the nodular and purpuric lesions of disseminated fungal infections caused by *Aspergillus*, *Candida*, and other less common agents.

DIAGNOSIS

Differential Diagnosis

The diagnosis of infectious exanthems frequently is considered an impossible task by many physicians. Other physicians glibly call the first maculopapular exanthem of childhood *roseola* and the first vesicular rash *chickenpox*, without consideration of more appropriate choices. The hallmark of diagnosis in exanthematous disease is careful elicitation of historical data. Differential diagnosis requires the consideration of noninfectious etiologies as well as different infectious agents. Listed in Table 58-17

are the major considerations in the diagnosis of diseases with cutaneous manifestations.

A history of exposure is most important in making a differential diagnosis. For example, was the patient exposed to poison ivy, insects, or a person ill with a specific disease? In infectious illnesses with high clinical expression rates (e.g., measles, chickenpox, and rubella), proper questioning usually reveals a contact case or at least other cases in the community. On the other hand, in illnesses with low rates of clinical expression of exanthem, such as adenoviral and some enteroviral infections, the source may not be apparent.

Consideration of the seasonal occurrence of different infectious agents, as well as insects, is particularly useful in making a differential diagnosis. In temperate climates, enteroviral and arthropod-mediated diseases occur in the summer and fall. Exanthems with measles, varicella-zoster, and rubella viruses occur most often in the winter and spring. The diagnosis of rubella is important because of fetal consequences. All too frequently, rubella is overdiagnosed and underdiagnosed, both of which can be avoided if its seasonal prevalence is understood.

The incubation period is important in separating the exanthem caused by rubella, varicella-zoster, or measles viruses from rash illnesses caused by enteroviruses or common respiratory viruses. The former have long incubation periods, whereas in the others, the period from exposure to the onset of illness is less than 1 week. Age can be useful. Today in the United States, measles and rubella often are illnesses of adolescents and young adults. Enteroviral exanthem frequency is related inversely to age.

Questioning to obtain a pertinent history of previous exanthems can give useful information if it is done with care. For example, if patients are asked whether they had rubella, the answer is quite unreliable. However, if the past illness is documented by year, season, and symptoms, accurate information often is obtained. The relationship of rash to fever is most significant in the diagnosis of roseola. The presence or absence of fever is important in separating exanthems of infectious and noninfectious etiology. Frequently, insect bites are diagnosed as chickenpox by parents and physicians as well. Chickenpox rarely occurs without fever.

The type and distribution of exanthem obviously are important. They virtually are diagnostic in hand, foot, and mouth syndrome, Rocky Mountain spotted fever, and atypical measles. Enanthem can lead to a specific diagnosis (Koplik spots in measles) or a category diagnosis (e.g., herpangina in enteroviral infections). Other characteristics, such as those listed in Tables 58-8 through 58-17, obviously are useful in delineating a specific illness.

Specific Diagnosis

As with other infectious diseases, establishing specific diagnosis depends on the acquisition of proper cultures, serologic tests, and microscopic study of secretions or histologic or cytologic preparations. These techniques are discussed in other chapters of this book.

Vesicular lesions always should be scraped for cytologic study or direct antigen identification (e.g., varicella and herpes simplex), and, frequently, petechial lesions should be scraped and stained in a search for infectious agents (e.g., meningococci). The etiology of viral infections can be established by isolation of virus, direct antigen detection, or serologic methods. In most instances, a virus recovered from the throat indicates acute infection and is the probable cause of a particular illness. Serologic study without culture is useful in diagnosing rickettsial diseases, some viral infections, and a few illnesses of bacterial origin. Serologic study without virus isolation generally is not useful in diagnosing enteroviral illnesses.

TREATMENT, PROGNOSIS, AND PREVENTION

The treatment, prognosis, and prevention of exanthematous diseases are presented in appropriate chapters throughout this text.

CHAPTER 59

Roseola Infantum (Exanthem Subitum)

James D. Cherry

Roseola infantum (i.e., exanthem subitum, pseudorubella, exanthem criticum, sixth disease, or 3-day fever) is a common, acute illness of young children characterized by a fever of 3 to 5 days' duration, rapid defervescence, and then the appearance of an erythematous macular or maculopapular rash that persists for 1 to 2 days.

HISTORY

Zahorsky[81] generally is given credit for the original description of roseola infantum. However, in his writings, he pointed out that the syndrome was described in earlier pediatric and dermatology texts.[82-84] Altschuler[1] observed that a British dermatologist, Willan, presented a description of the illness in his 1809 book *On Cutaneous Diseases*. The descriptions in the older literature did not separate the syndrome from the known exanthematous diseases (i.e., measles, rubella, and scarlet fever), an omission that Zahorsky corrected.

In 1921, Veeder and Hempelmann[75] described the syndrome further and noted that leukopenia and relative lymphocytosis occurred. These investigators objected to the name *roseola infantum*, which in the past had been used to describe a large group of diseases with indefinite causes. They suggested the term *exanthem subitum* because it was "descriptive of the most striking clinical symptom, namely, the sudden, unexpected appearance of the eruption on the fourth day." Currently, the term *roseola* is used most commonly to describe the syndrome.

From 1920 through 1940, many excellent clinical descriptions of the syndrome were published.* From 1940 through 1988, articles relating to roseola were concerned with unusual manifestations and complications† and attempts to recover an etiologic agent.[26,30,40,45,64] In 1951 and 1954, Neva and associates[50-52] noted the association of a roseola-like illness and infection with echovirus 16. This association was noted again in 1974.[27] In 1988, Yamanishi and associates[79] identified human herpesvirus–6 (HHV-6) in the blood of infants with roseola, and since then the association between this virus and the disease has been confirmed on many occasions.‡ HHV-7 also has been found to be the cause of many cases of roseola.§

EPIDEMIOLOGY

In his original article, Zahorsky[81] reported that roseola occurred most commonly in the fall. In his second article, he observed a year-round incidence[82]; in 1925, he pointed out that most cases occurred in the spring, summer, and fall.[83] Breese[10] noted that the greatest number of cases occurred in the summer and early fall. In contrast, 55

percent of Clemens' cases occurred in February, March, and April; 16 percent were seen in October.[17] In a review of 243 cases during a 10-year period, Juretic[38] observed that the peak month was May. Juretic also reviewed the seasonal incidence in 10 other studies and found only minor variations by month. Prevalence was greatest in March, April, and October and least in December. One epidemic of roseola in a maternity hospital occurred in the summer,[36] another epidemic in an infants' home occurred in the fall,[6] and a hospital outbreak occurred in the winter.[18]

Roseola predominantly is an illness of young children. It occurs rarely in infants younger than 3 months old or children older than 4 years. In a review of 1462 cases, the peak age range prevalence was 7 to 13 months of age; 55 percent of the cases occurred within the first year of life, and 90 percent occurred within the first 2 years of life.[38] Occasionally, cases have been seen in older children, adolescents, and young adults and in neonates and other infants younger than 6 months.[24,36]

Although Faber and Dickey[20] found twice as many girls as boys with the syndrome, the sex ratio in most large studies has been equal.[7,10,17,24,45] Although three epidemics have been reported, and cases frequently occur in groups by season, most cases occur sporadically without known exposure. The syndrome, when seen sporadically, generally is considered to be noncontagious, but secondary cases have been reported occasionally.[6,10,18,36] The incubation period range in epidemics is 5 to 15 days.[6,10,18]

The attack rate of roseola has not been well studied. Berenberg and associates[7] stated that roseola is the exanthem most commonly encountered in children younger than 2 years old. Breese[10] found that 16 percent of a group of infants he followed for the first 12 months of life had definite roseola. He estimated that 30 percent of children would have clinical roseola. Juretic[38] looked at the frequency of roseola in 6735 children; the yearly attack rate during a 10-year period ranged from 1 to 10 percent, with a mean of 3.3 percent.

ETIOLOGY

In 1941, Breese[10] reported vigorous attempts to isolate a filterable virus from three children with pre-eruptive roseola. These studies included extensive animal inoculations, but no viral agents were uncovered. In 1950, Kempe and associates[40] reported the passage of the illness to a 6-month-old susceptible infant by the intravenous injection of serum from an 18-month-old child with pre-eruptive roseola. Febrile illnesses without exanthem also were produced in monkeys with serum and throat washings from a child with the syndrome. In similar experiments, Hellstrom and Vahlquist[30] produced the syndrome in three children aged 6 to 9 days after the intramuscular administration of blood from typical roseola cases.

In electron microscopy studies, Reagan and associates[61] observed uniform viruslike particles (100 to 110 nm) in the blood of an 18-month-old child with the syndrome. Febrile illness was produced in two monkeys after concentrated virus-containing material was inoculated.

Since the advent of modern diagnostic virology in the early 1950s, numerous viral agents have been recovered from children with roseola. In 1951, Neva and associates[52] studied an epidemic exanthematous illness (i.e., Boston exanthem) caused by echovirus 16, in which many of the illnesses were characteristic of roseola. In 1954, Neva[50] observed additional cases of roseola-like illness associated with echovirus 16 infection. In 1974, Hall and colleagues[27] reported four additional echovirus 16 infections with clinical manifestations of roseola. The reporting of roseola in Rochester, New York, nearly doubled during the time of echovirus 16 activity in the area. Roseola-like illnesses that also have been associated with enteroviruses are caused by coxsackievirus A6, A9, B1, B2, B4, and B5 and echovirus 9, 11, 25, 27, and 30.[15,16,27,66,78] Outbreaks of roseola that occur in the summer and fall probably are caused by enteroviral infections.

In addition to enteroviruses, adenovirus types 1, 2, 3, and 14 and parainfluenza type 1 virus have been recovered from children with roseola.[23,37,51,78] Saitoh and associates[64] detected rotavirus capsomeres in fecal specimens of nine children with roseola. In contrast to these findings, Gurwith and colleagues[26] studied fecal specimens from five children with roseola, and in none were viral particles identified. One of 13 children in this study did develop antibody to rotavirus around the time of illness, however. In addition to the occurrence of roseola associated with numerous natural viral infections, its pattern (i.e., fever and then rash with defervescence) was observed frequently in recipients of Edmonton B measles vaccine.[15]

In 1988, Yamanishi and associates[79] isolated HHV-6 from four infants with roseola and all four had significant titer increases for this virus. Shortly after this finding was reported, several other investigators noted similar findings.* The implication from these studies, as suggested by the various investigators, is that HHV-6 is the cause of roseola. This viewpoint overlooks or ignores the past experience in which other viral agents have been associated with the clinical syndrome. Subsequent studies indicate that HHV-6 is a major cause of roseola and the cause of acute febrile illness without exanthem in infants.† Since 1993, HHV-7 has been accepted as an additional causative agent in roseola.‡

In a study of 1653 infants and young children with acute febrile illnesses, Hall and colleagues[27] found that 160 (9.7%) had primary HHV-6 infections; 27 (17%) of the children who were infected with HHV-6 had roseola. Zerr and associates[86] identified 80 children with primary HHV-6 infections, and of these, 30 percent had roseola. In the same population-based study, 3/80 (4%) children without primary HHV-6 infection also had roseola. In a study of clinical roseola, Okada and associates[54] found that 81 percent had serologic evidence of HHV-6 infection, and that 8 percent had an echovirus-18 infection. In a study of roseola in Italy, Braito and Uberti[9] found

*References 2, 5, 19, 33, 41, 69, 73.

‡References 3, 15, 31, 68, 71, 77.

serologic evidence of HHV-6 infection in only 30 percent of the cases. In 33 percent of the remaining cases, they attributed the illnesses to another infectious agent. In 1994, Hidaka and associates[31] estimated that 73.5, 10.2, and 16.3 percent of their roseola cases were caused by HHV-6, HHV-7, and other viruses, respectively. In a study of HHV-6 infections in young Brazilian children with rashes it was noted that only 21 percent had typical roseola.[76] In summary, HHV-6 is an important cause of roseola, but not the only cause.

PATHOPHYSIOLOGY

The pathophysiology of roseola is unknown. Watson,[78] in the pre–HHV-6 era, suggested that roseola is not an infection caused by one particular pathogen, but is the result of an immunizing reaction against many different viruses. He also suggested that the rash is caused by the neutralization of virus in the skin at the end of the period of viremia.

Viremia is common in HHV-6, HHV-7, enteroviral, and adenoviral infections; thus, a reasonable conclusion (as originally suggested by Watson[78]) is that the rash in roseola is related to an immunologic event resulting from the virus that is localized in the skin. Why the pattern of fever and then rash with defervescence is so clearly age-dependent is unknown. Most of the viruses that in the past have been associated with roseola cause other exanthematous manifestations in older patients.[15]

CLINICAL PRESENTATION

The basic clinical pattern of roseola is a febrile period of 3 to 5 days, defervescence, and the appearance of a rash that persists for 1 to 2 days. Because the syndrome is caused by many different viruses, the illness apparently may be associated with numerous other signs and symptoms. The major manifestations have been reviewed elsewhere.*

Illness usually occurs with the apparent abrupt onset of fever. Slight irritability and malaise occur frequently, but more commonly, the child's temperature is taken because a parent notices that the child feels warm. The temperature usually is in the range of 38.9° to 40.6°C (102.2° to 105°F). Despite the high fever, the child usually is active, alert, and generally unfazed. The fever is constant or intermittent, with its greatest degree occurring in the early evening. Restlessness and irritability occur with higher temperatures. The usual duration of fever is 3 to 5 days, but it has persisted for 9 days. The temperature most often returns to normal by crisis, but in some cases, temperature "lysis" occurs over the course of 24 to 36 hours.

Mild cough and coryza are seen frequently in cases occurring in the winter and spring. Headache and abdominal pain are reported in older children, mainly in the summer and fall. Vomiting and diarrhea occur infrequently.

On initial physical examination during the febrile period, most children appear to be happy, alert, and playful. With high temperatures, some children are irritable; occasionally, a child appears to be sick, which suggests more serious illness, such as meningitis or septicemia. Examination within the oral cavity frequently reveals one or more abnormalities. Mild inflammation of the pharynx and tonsils occurs most commonly. Occasionally, small exudative follicular lesions are noted on the tonsils. In other cases, small ulcerative lesions on the soft palate, uvula, and tonsillar pillars are observed. Usually, the lesions on the soft palate consist of only erythematous macules and maculopapules, presumably because of lymphoid hyperplasia.

Mild injection of the tympanic membranes occurs commonly. Enlargement of the suboccipital, posterior cervical, and postauricular lymph nodes is a common finding, but the degree is not remarkable.

Berliner[8] noticed that children with roseola had palpebral edema. He suggested that the "heavy eyelids" or "droopy" or "sleepy" appearance resulting from this edema was diagnostic of the syndrome before the appearance of the rash. Bulging of the anterior fontanelle also has been observed in roseola.[56]

Appearance of the rash in roseola usually coincides with the subsidence of fever, but it may occur after an afebrile interlude of several hours to 2 days. When defervescence occurs by lysis, onset of the exanthem can occur before the temperature has returned entirely to normal. By definition, it is incorrect, however, to call an illness roseola if the fever and rash are truly concomitant.

Zahorsky[81,82] originally described the rash as morbilliform, but his use of *morbilliform* was not the same as is used today (i.e., measles-like, erythematous, maculopapular with confluence). The rash is erythematous and macular or maculopapular, and the lesions are discrete. The lesions are 2 to 5 mm in diameter and blanch on pressure. Frequently, individual lesions are surrounded by a whitish ring. The rash is most prominent on the neck and trunk, but the proximal extremities and the face also may be affected. Although they have been reported,[17,25] pruritus and desquamation usually do not occur. The rash usually persists for 24 to 48 hours. In occasional cases, well-documented rashes have been observed to appear and resolve within 2 to 4 hours. Yoshida and associates[80] described a 7-month-old boy with HHV-6 infection and typical roseola initially. On the ninth day of illness, vesicular lesions appeared on the face and limbs, however. These lesions persisted for 12 days.

Except for the white blood cell count, routine laboratory studies are of little use in roseola. The total white blood cell count usually is low. Early in the febrile period, high counts occasionally are found, however. The total count reaches its nadir by the third to sixth day of illness and then gradually returns to normal over the ensuing 7 to 10 days. During the same time frame, the percentage of lymphocytes increases from a normal value of about 50 percent to 60 to 80 percent on days 3 to 10 and then returns to normal over the next 7 days. Frequently,

*References 7, 10, 17, 24, 38, 82.

extreme counts in the range of 3000 cells/mm^3 with 90 percent lymphocytes are found, which raises the consideration of a granulocytic defect.

CLINICAL COMPLICATIONS

The most important complications of roseola are convulsions and other neurologic symptoms.* The incidence of convulsions has varied widely among reports. Juretic[38] did not find one instance of convulsions in the 243 cases in his study. Breese[10] did not report convulsions in any of 100 roseola attacks that he studied. In contrast, Greenthal[24] noted convulsions in 6 percent of his cases, and Faber and Dickey[20] found seizures in 8 of 26 cases of roseola. Möller[48] observed that 8 percent of children admitted to the hospital because of febrile convulsions eventually were diagnosed with roseola infantum.

Möller[48] also reported cerebrospinal fluid evaluations in 29 cases of roseola and febrile convulsions. In six instances, the pressure was elevated; in two, there were 5 white blood cells/mm^3; and in another instance, there were 9 white blood cells/mm^3. In most other cerebrospinal fluid examinations, the findings have been normal, but mild pleocytosis with mononuclear cells has been identified occasionally.[7,32] A surprising number of cases of encephalitis associated with roseola have been reported,[13,22,32,35] and residua have been common. Hemiplegia has occurred after illness,[13,22,59,62] and permanent paresis and mental retardation have occurred in some affected patients. The syndrome of inappropriate secretion of antidiuretic hormone has been reported in roseola associated with HHV-6 infection.[55,65] Facial nerve palsy and Guillain-Barré syndrome also have been noted after HHV-6 induced roseola.[47,57]

Thrombocytopenic purpura was noted in one report in five children with roseola; all of these patients recovered.[53] In a more recent study, Hashimoto and colleagues[29] noted five children with thrombocytopenia during the acute phase of roseola caused by HHV-6 infection. Their data suggested that the thrombocytopenia was due to bone marrow suppression, rather than immune-mediated peripheral consumption. A 14-month-old girl developed a generalized eruptive histiocytoma with rapid progression and then resolution after roseola.[70]

*References 2, 7, 11-13, 20, 22, 25, 32, 35, 43, 48, 59, 62, 63.

DIAGNOSIS

Although detecting leukopenia with relative lymphocytosis is fortuitous, the only necessity in establishing the diagnosis of roseola is to document the fever, defervescence, and exanthem pattern. Frequently, the first exanthematous illness that a child has is called roseola, regardless of whether the exanthem and the fever are concomitant, or the child has no febrile period at all.

The only problem in the differential diagnosis occurs when a febrile child is receiving antibiotics and a rash follows defervescence. This event occurs frequently, and the child usually is labeled allergic to the antibiotic, rather than suspected of having roseola. In most instances of drug allergy, the exanthem lasts longer than roseola does, and in allergic cases, pruritus and fever may accompany the rash.

TREATMENT AND PROGNOSIS

No specific treatment for roseola exists. When fever is a problem, it may be treated with acetaminophen. Acetaminophen can alter the temperature curve, possibly obscuring the correct diagnosis. Febrile seizures and other neurologic complications should be treated vigorously.

In most cases, the outlook is excellent. When encephalitis occurs, the prognosis must be guarded. Because roseola is the result of infection with multiple different viruses, no practical way to prevent it exists.

CHAPTER 60

Skin Infections

60A ■ BACTERIAL SKIN INFECTIONS

Mary Anne Jackson

NORMAL SKIN

Anatomy

The epidermal skin layer provides the primary barrier to invasion by microorganisms and an interface between the body and the environment. Hair follicles, sebaceous glands, nails, and sweat glands are considered epidermal appendages and as such may be involved in skin infection. A dermal layer composed of collagen and elastic fibers gives skin its elasticity; however, other cell elements that are present, including mast cells, blood and lymph vessels, and cutaneous nerves, may be involved in the inflammatory process in response to infection. The subcutaneous fat layer is just beneath the dermis and contributes primarily to thermal stability, but it also may be involved when infection extends beyond the epidermal–dermal layer.

Flora

Colonization is defined as the presence of a microorganism on the skin without either clinical signs or symptoms of infection at the time of isolation. Normal bacterial skin colonization is divided into resident and transient flora. Resident flora predominates and includes typical nonpathogens, such as *Staphylococcus epidermidis* and *Propionibacterium acnes*, in addition to other anaerobic diphtheroids and micrococci. Transient flora include pathogenic organisms, such as *Staphylococcus aureus*, streptococci, gram-negative enteric organisms, and *Candida albicans;* these pathogens usually are present in smaller numbers than the resident flora and may be removed by skin cleansing. Acutely or chronically damaged skin, contact with animate and inanimate environmental sources, and exposure to antimicrobial agents or indwelling devices can modify the skin flora and predispose to infection by resident or acquired transient flora.[78,88]

CUTANEOUS INFECTION AND DERMATOLOGIC MANIFESTATIONS OF SYSTEMIC DISEASE

Dermatologic manifestations of infection can occur when the skin is infected primarily or as a secondary phenomenon. Prompt diagnosis and treatment of certain systemic or disseminated diseases may be accomplished when the secondary dermatologic manifestations are recognized. Empirical treatment of systemic diseases such as endocarditis (septic emboli) or septicemia caused by bacterial pathogens, such as *Neisseria meningitidis* or *Pseudomonas aeruginosa*, is possible when the dermatologic manifestations (i.e., purpura fulminans, ecthyma gangrenosum) are noted. Generalized viral infections may be heralded by pathognomonic skin findings, such as occur in varicella or measles. Alternatively, skin manifestations may be mediated by toxin (staphylococcal scalded skin syndrome or toxic shock syndrome) or by immunologic mechanisms (gonococcemia).

The list of bacterial infectious agents associated with skin infections is extensive (Table 60A-1). This section focuses on the bacterial skin infections most frequently encountered by practicing clinicians. Viral, bacterial, and fungal systemic or disseminated diseases are categorized in Chapter 58 and are also presented in the specific chapters in Part III of this book.

IMPETIGO

Nonbullous or Simple Superficial Impetigo

The bacterial skin infection most commonly encountered in children is nonbullous impetigo, which accounts for more than 70 percent of impetigo cases in children. This superficial infection is seen predominantly in summer, with insect bites, cutaneous injuries, and primary dermatitis serving as the portal of entry.[45,60]

Nonbullous impetigo, sometimes called *thick crusted impetigo*, is characterized by the appearance of erythematous maculopapules that rapidly evolve from a vesicular to a pustular stage. Centrally crusted plaques range in size from a few millimeters to 1 cm and are surrounded by a distinct margin of erythema. The honey-colored crust is a classic feature, and removal of the crust results in the reaccumulation of fresh exudate. Regional lymphadenopathy can occur and often is the reason that the patient seeks medical attention. Spread to exposed areas, usually the face, neck, and limbs, occurs frequently. This form of pyoderma often is associated with a 2- to 3-week delay

TABLE 60A-1 Bacterial Infectious Agents Associated with Cutaneous Manifestations

Anthrax	*Bacillus anthracis*
Blistering dactylitis	*Streptococcus pyogenes*
	Streptococcus agalactiae
	Staphylococcus aureus
Cellulitis	*S. pyogenes*
	S. aureus
	Haemophilus influenzae type b
	Streptococcus pneumoniae
Chancroid	*Haemophilus ducreyi*
Diphtheria	*Corynebacterium diphtheriae*
Ecthyma gangrenosum	*Pseudomonas aeruginosa*
Erysipelas	*S. pyogenes*
	S. agalactiae; groups C, G streptococci
	S. pneumoniae
Erysipeloid	*Erysipelothrix rhusiopathiae*
Folliculitis	*S. aureus*
	Coagulase-negative staphylococci
	Klebsiella spp
	Enterobacter spp
	Escherichia coli
	P. aeruginosa
	Proteus spp
Erythrasma	*Corynebacterium minutissimum*
Furunculosis	*S. aureus*
Hidradenitis suppurativa	*S. aureus*
	Streptococcus milleri
	E. coli
	Anaerobic streptococci
Granuloma inguinale	*Calymmatobacterium granulomatis*
Impetigo	
Simple superficial	*S. aureus*
	S. pyogenes
Bullous	*S. aureus*
Lymphogranuloma venereum	*Chlamydia trachomatis*
Melioidosis	*Burkholderia pseudomallei*
Necrotizing fasciitis	*S. pyogenes*
	Polymicrobial
Nocardiosis	*Nocardia brasiliensis*
	Nocardia asteroides
Paronychia	Polymicrobial
Perianal dermatitis	*S. pyogenes*
Pitted keratolysis	Coryneform bacteria
Syphilis	*Treponema pallidum*

Entries in bold are discussed in the text.

in establishing the diagnosis because the lesions are slow to progress, only mildly tender at the site of the lesion, and generally not associated with systemic signs or symptoms.

Nonbullous impetigo classically has been associated with infection caused by group A β-hemolytic streptococcus. More recent data underscore the importance of *S. aureus*, however, which now accounts for most cases of nonbullous impetigo in the United States.[6,49]

Primarily a disease of children, nonbullous impetigo is spread within families and by close physical contact. It is prevalent during warm, humid seasons and is seen year-round in tropical regions. Endemic disease occurs in the southeastern United States and Hawaii.

Epidemics of streptococcal impetigo have been associated with postinfectious glomerulonephritis, and streptococcal strains, including types 2, 31, 49, 53, 55, 56, 57, and 60, have been implicated in such outbreaks.[66,106] Studies published in the 1950s and 1960s from the Red Lake Indian Reservation in Minnesota first confirmed the association of impetigo in school-aged children with a postinfectious nephritis that occurred 18 to 21 days after the onset of impetigo and implicated the so-called Red Lake strain, M-type 49.[5] Further studies in this population performed in the early 1970s found that group A β-hemolytic streptococcus was isolated from normal skin in 23/31 high-risk children a mean of 10 days before the development of impetigo.[33] Local trauma and other environmental factors seemed to explain the predilection of exposed skin to streptococcal infection, especially the skin of the legs, where 62 percent of the total lesions were noted. Secondary acquisition of streptococcal isolates in other family members occurred a mean of 5 days after the primary case, a time frame that was noted to be significantly shorter than that of secondary respiratory acquisition.[51] Rheumatic fever does not occur as a postinfectious sequela of streptococcal skin infection.

Cutaneous botryomycosis, an indolent infection reminiscent of crusted impetigo, usually is caused by *S. aureus*. Characterized by plaquelike lesions with superficial pustules and crusts, this entity has a predilection for patients with altered immune function.[22] Histologic examination may suggest the diagnosis of actinomycosis if a granulomatous lesion with granules resembling those seen with *Actinomyces* is noted. Successful treatment can be accomplished after the bacterial pathogen has been identified.

Bullous Impetigo

Bullous impetigo is diagnosed when the primary lesion begins as small vesicles and later appears as flaccid, painless bullae, generally measuring greater than 1 cm (Fig. 60A-1). Initially filled with clear fluid, the lesions eventually may exhibit a purulent fluid level. Rupture of the thin bullae usually reveals a moist, erythematous base that dries to a shiny lacquer-like appearance, sometimes described as a varnished finish (Fig. 60A-2). Systemic toxicity is not seen except in neonates, in whom disseminated disease may occur.

In contrast to thick, crusted impetigo, in virtually all cases of bullous impetigo, staphylococci are isolated in pure culture from aspirated bulla fluid. Other bullous dermatitides of childhood, such as pemphigus or Stevens-Johnson syndrome, may be excluded by isolation of the organism. Occasionally, biopsy is done in cases in which extensive bullae or an atypical clinical appearance is noted. Confirmation of a cleavage plane high in the

epidermis with gram-positive organisms and polymorphonuclear leukocytes present is a definitive diagnosis of bullous staphylococcal disease.

Infection generally is caused by phage group II strains, particularly phage type 71, but also 3A, 3C, and 55, which are noted to elaborate epidermolytic toxins A and B. Pathologically, these toxins act by disrupting the intercellular attachment of epidermal cells of the stratum granulosum. The toxin is thought to function as a protease in separating the upper layers of the epidermis of adult and infant human skin. Production of antibody to epidermolytic toxin occurs with age; however, it does not protect against the development of new bullous lesions during the localized impetiginous stage of this staphylococcal disease.

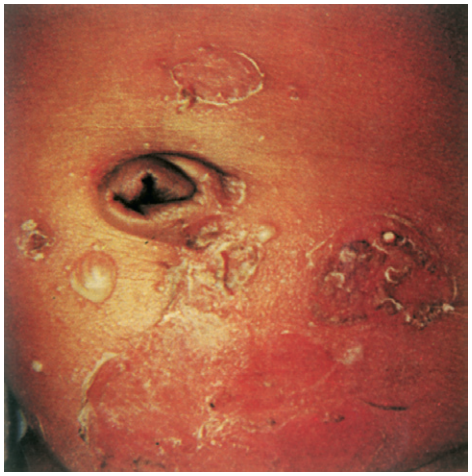

FIGURE 60A-1 ■ Bullous impetigo in a newborn infant caused by exfoliative toxin-producing *Staphylococcus aureus.* (See companion Expert Consult website for color version.)

Epidemiologically, large outbreaks of bullous impetigo have been traced most notably to hospital nurseries, where identification of infected infants always occurs within the first month of life but after the infant has been sent home. A more severe, generalized form of the epidermolytic toxin-mediated disease (Ritter disease) may be seen in a few infants during one of these outbreaks, underscoring the importance of infection control surveillance practices in recognizing such an outbreak (Fig. 60A-3).

Treatment of Impetigo

Topical mupirocin may be used in cases of nonbullous impetigo in which adequate coverage of the affected sites can be ensured.[17,32,97] In other cases, systemic treatment with an oral antistaphylococcal antimicrobial agent, such as cephalexin, should be employed.[37,38,44,108] As in other staphylococcal diseases, an increase in

FIGURE 60A-2 ■ Flaccid bullae and shiny lacquer base of staphylococcal impetigo.

FIGURE 60A-3 ■ Typical appearance of a neonate with Ritter disease.

community-acquired, methicillin-resistant *S. aureus* (MRSA) cases has been noted in the last decade.[61,62,71,123] In cases for which traditional antistaphylococcal agents are unsuccessful or in patients with recurrent disease, culture should be done to identify the bacterial strain and susceptibility pattern. Currently, the majority of community-acquired MRSA isolates are susceptible to clindamycin, but sensitivity patterns vary throughout the United States.[16,23]

PERIANAL STREPTOCOCCAL DERMATITIS

Formerly called *perianal cellulitis*, perianal streptococcal dermatitis, a commonly recognized superficial skin infection, is characterized by the presence of marked, well-demarcated, perirectal erythema with associated swelling, pruritus, and tenderness but an absence of systemic symptoms or progressive disease. Approximately half of patients complain of significant rectal pain on defecation, and a third note blood in their stools.[4,28,69,96]

Heavy growth of group A β-hemolytic streptococcus is seen on perianal culture, and in one study, isolation of a specific T-type *Streptococcus* (T 28) raised the question of whether certain streptococcal strains have tropism for the perineal region.[102] Asymptomatic patients were evaluated in two studies, and only sparse growth of group A β-hemolytic streptococcus was noted in 6 percent of cases.

Perianal streptococcal dermatitis is treated with oral penicillin agents. Topical mupirocin also has been used successfully. Recurrences are noted commonly, however. In one large series of patients, one third had recurrent disease.[85] Intrafamilial spread of disease frequently occurs and may provide a vector for recurrence. For patients with recurrent or persistent disease, clindamycin or a β-lactam agent plus rifampin may be used, and identification and treatment of other affected family members may be necessary.

BLISTERING DISTAL DACTYLITIS

Most commonly identified in school-aged children, blistering distal dactylitis is a distinctive superficial skin infection classically associated with group A β-hemolytic streptococcus.[12] Bullae 2 cm in diameter develop over the anterior fat pad of the distal phalanges, sometimes extending to involve the nail folds. Involvement of the proximal phalanges or the palms occasionally is noted. Frankly pustular lesions may occur, but the lesions themselves usually are asymptomatic or only mildly tender. A thin purulent exudate generally is apparent on incision and drainage.[70]

The diagnosis is confirmed by recovery of the etiologic agent on culture, most commonly group A β-hemolytic streptococcus, although group B streptococcus and *S. aureus* also have been noted.[57] Concurrent recovery of group A β-hemolytic streptococcus in the pharynx has been reported in a few cases. Treatment includes a 10-day course of an oral β-lactam agent, usually penicillin or amoxicillin, in addition to incision and drainage of any tense bullae.

ERYSIPELAS

The superficial cellulitis erysipelas, referred to as *St. Anthony's fire* in the Middle Ages, is characterized by the appearance of a bright erythematous plaque with a distinct, elevated border that sharply demarcates affected from unaffected skin. The lesion most often involves the face or lower extremity, although extensive involvement of the trunk has been noted. The involved skin is warm and tender and may have a peau d'orange appearance. Large tension bullae may be seen in the erythematous zone.[64] The patient generally appears toxic and is highly febrile, and rapid extension of the affected skin may occur over the course of hours.[30,65,135]

Histopathologic findings include intense edema with vascular dilation of the dermis and uppermost subcutaneous tissue. Involvement of lymphatic channels and tissue spaces with polymorphonuclear leukocytes is a typical finding.

Surgical wounds, the umbilicus of the neonate, or any break in the skin may serve as the portal of entry; however, the initial lesion may be inapparent. Localized edema, such as occurs from a renal or lymphatic source, is a predisposing factor, and antecedent respiratory tract infection often is reported. An increased risk for development of erysipelas has been noted in patients with hypogammaglobulinemia, certain malignancies such as lymphoma, or lymphedema complicating radiation therapy.

The diagnosis generally is recognized on clinical grounds, and group A β-hemolytic streptococcus traditionally has been isolated by aspiration of the advancing margin of the lesion. A few case reports have identified other streptococci (including groups B, C, and G), *Moraxella* spp., *Haemophilus influenzae*, and *Streptococcus pneumoniae* as etiologic agents.* A combination of intravenous penicillin and clindamycin should be used until the results of culture are available. Erysipelas has a classic clinical appearance, and appropriate diagnosis and therapy result in a prompt clinical response in most cases. Penicillin prophylaxis may be considered for patients with recurrent erysipelas, particularly patients with underlying risk factors.[15,39]

ECTHYMA

Ecthyma gangrenosa is a deep-seated infectious process that manifests as a necrotic ulcer covered by a black eschar. Usually, the initial lesion, a vesicopustule, sits on an erythematous base; it eventually erodes through the epidermis to the dermis, where it forms a crusted ulcer with heaped-up borders and then becomes frankly necrotic.[63]

This process rarely occurs in an otherwise healthy child, and if it does, an immunodeficiency workup should ensue. *Chromobacterium violaceum* has been reported to cause ecthyma and similarly should result in an immunologic evaluation focusing on neutrophil defects, including disorders such as chronic granulomatous disease.[21]

Ecthyma can occur as a primary cutaneous infection in an immunocompetent host, and other etiologic agents that have been confirmed include *S. aureus*, *Aeromonas hydrophila*, and group A β-hemolytic streptococcus.* A similar-appearing lesion is seen with cutaneous anthrax; however, extensive nonpitting edema of the surrounding soft tissues is an important clue to this diagnosis. Ecthymatous-like lesions have been seen in patients with herpes simplex infection.[83] Additionally, human orf infections result in ulcerative skin lesions that appear similar to lesions of ecthyma; the clue to establishing the diagnosis is contact with an infected animal, usually sheep or goats, or a contaminated fomite.[25]

When an ecthymatous lesion is noted in a febrile neutropenic host, it generally signals disseminated infection. *P. aeruginosa* is the etiologic pathogen identified most commonly in such cases, but other gram-negative pathogens and fungi, including *Enterobacter*, *Escherichia coli*, *Morganella*, *Pseudomonas cepacia*, *Serratia marcescens*, *Stenotrophomonas maltophilia*, *Aspergillus*, *Mucor*, *Fusarium*, and *C. albicans*, have been implicated in ecthyma gangrenosum in compromised hosts.† Ecthyma has been seen as the heralding manifestation of acute lymphoblastic leukemia in children.[110] Empirical antimicrobial therapy for ecthyma gangrenosum in a neutropenic host should include intravenous therapy with an anti-*Pseudomonas* agent plus an aminoglycoside. Biopsy of the lesion may provide more specific etiologic information and allow for confirmation of antimicrobial susceptibility.

FOLLICULITIS, FURUNCULOSIS, AND CARBUNCLES

Folliculitis, furunculosis, and carbuncles represent a group of infections characterized by their origin in the hair follicles and the formation of abscesses. Virtually always caused by *S. aureus*, these infections were seen commonly in the 1950s in disease that often involved multiple family members. Outbreaks among athletes likewise have been reported.[129]

By definition, these infections involve sites where body hair is present, including the axilla, breast area, perineum, neck, and extremities. Lesions of folliculitis represent abscesses of a single hair follicle with limited surrounding tissue involvement. When deeper inflammatory nodules are associated with tissue edema, furunculosis is diagnosed. When several interconnecting furuncles are present, the lesion is referred to as a carbuncle. Generally, older children and adolescents are predisposed to the development of follicular infections, and individuals with diabetes mellitus, abnormal neutrophil chemotaxis, and impaired circulation may have recurrent disease.

Although *S. aureus* nearly always is the cause of folliculitis as in the past, outbreaks of so-called hot tub

*References 14, 29, 41, 86, 100, 122, 136.

*References 47, 56, 72, 82, 94, 103, 133.
†References 36, 50, 52, 95, 105, 111, 116, 121.

folliculitis have been described and almost always are caused by *P. aeruginosa;* rarely, other gram-negative organisms have been reported.[26,27] Folliculitis in an immunocompromised host often is caused by unusual fungal pathogens.[3,114,126] Although typically associated with hot tubs and whirlpools, a large outbreak of *Pseudomonas* folliculitis reported in 1984 involved 117 individuals after swimming in an indoor pool. An incubation period of 24 to 30 hours could be ascertained, and a typical follicular, pustular eruption was noted. The mean duration of the folliculitis, 15 days, is consistent with other reports, but some patients continued to complain of rash for weeks, and recurrent pustules appearing months later have been reported in other studies.[55]

A more recent report has identified four cases of *Mycobacterium fortuitum* complex furunculosis that developed after pedicures, suggesting this pathogen may be added to the differential diagnosis in such cases when a patient presents with nonhealing furuncles on the lower legs, especially when bacterial cultures have been negative, or the disease is unresponsive to antistaphylococcal therapy (including MRSA).[113] Early recognition and institution of appropriate therapy are essential, and the history of pedicures may be a clue to establishing the diagnosis. Cutaneous myiasis has been reported to manifest as a chronic boil or furuncle, but the diagnosis should be considered only in such cases in which an appropriate travel history is elicited.[31]

Recognition of the typical skin lesion usually is sufficient to establish the diagnosis. Unless the patient has a history of exposure to a hot tub or whirlpool, or recently has had a pedicure, a regimen of antistaphylococcal therapy should be sufficient. In the era of MRSA infection, local susceptibility profiles should be used to confirm appropriate therapy. Isolated boils resolve with drainage alone. Systemic therapy may be considered in cases in which lesions are large or multiple. Trimethoprim-sulfamethoxazole is a good choice for a nontoxic patient older than 2 months. Clindamycin is a good choice for most locales, although resistance may be increasing.[80,89] Because MRSA now accounts for 75 percent of cases in which children present with skin and soft tissue infection, treatment should be individualized, based on type of presentation, patient age, and underlying disease.[79] Systemic agents should be used for 7 to 10 days in patients who are toxic, who have extensive disease, or who have associated cellulitis. Large lesions, specifically larger than 5 cm, should be incised and drained, and culture should be done in all cases to confirm susceptibility testing. In some patients, hematogenous metastatic spread may occur, and a search for foci in the heart, bones, joints, deep tissues, or brain should be done in patients with significant systemic toxicity.

For patients in whom recurrent disease develops, chronic dermatoses, such as eczema, should be identified, and in obese adolescents, the diagnosis of diabetes mellitus should be considered.[7] The patient should be cautioned to refrain from sharing washcloths or towels, and skin trauma and use of irritants such as deodorants should be avoided.

The utility of decolonizing regimens with topical agents, such as mupirocin (nares and perianal area) and chlorhexidine or bleach baths (skin), may be considered in certain cases. *S. aureus* colonization of the nares, rectum, or skin can be detected by culture of these areas, but confirmation of carriage is likely necessary only in specific cases for which decolonization is desirable. The indications for and benefit of decolonization vary depending on host factors, underlying disease, and circumstances related to the health care setting.[125] Outbreaks of MRSA colonization or infection require a multifaceted approach, including attention given to hand washing, cohorting, barrier measures, and decolonization strategies. Examples of special circumstances include the following: (1) patients who are immunosuppressed and colonized and at risk for development of systemic infections; (2) patients who are more likely to spread the organisms, owing to behavior (e.g., mentally retarded patients); or (3) patients who have repeated infections caused by the MRSA strain they carry.

Most children with recurrent furunculosis are otherwise healthy, and no specific immunologic evaluation is necessary; however, cases of recurrent furunculosis in patients with hyper-IgE syndrome and common variable immunodeficiency have been reported, and an association with mannose-binding lectin deficiency was confirmed in a family.[76,81,124] Rarely, children with white blood cell defects may have recurrent staphylococcal skin abscesses, and tests of white blood cell function may be considered in specific patients. Data suggest that vitamin C may be beneficial in cases of recurrent folliculitis.[91,92]

HIDRADENITIS SUPPURATIVA

Hidradenitis suppurativa, a chronic, debilitating condition, is a disorder of the apocrine glands that involves primarily skin in the axilla and anogenital region, although scalp, umbilical, and breast involvement has been reported. Seen mainly in adolescents, this androgen-dependent condition is manifested by the development of multiple painful nodules and the formation of deep abscesses in the skin in areas where apocrine glands are present. The formation of fistulas, ulcers, and contracted scars may complicate the course, and recurrent relapses may be noted. Infection usually is polymicrobial, and pathogens to consider include *S. aureus*, gram-negative enteric organisms, and anaerobes. Drainage of abscesses and institution of systemic antimicrobial therapy may be necessary. When fistulas associated with anogenital disease develop, adjacent structures, including the urethra, bladder, and rectum, may be involved. Surgery usually is required for cure. Carbon dioxide laser treatment in some cases may be beneficial.[87]

CELLULITIS

The diagnosis of cellulitis is made when the subcutaneous tissues and dermis are involved in a clinical process manifested as localized edema, erythema, warmth, and tenderness of the tissues. The leading edge of the involved site may be notable, but it is not raised and well demarcated as in erysipelas.

Infection usually is caused by coagulase-positive staphylococci and group A β-hemolytic streptococcus; however, infection also is caused by group B streptococcus (neonates) and *S. pneumoniae*, and, in the past, *H. influenzae* type b cellulitis was described.[130] Streptococcal and staphylococcal cellulitis can involve patients of any age and any site, although the extremity is noted most often. Frequently, the patient has a history of antecedent trauma at the site of involvement, but the injury may not have appeared significant. Some researchers advocate culture of the cellulitic site, but in practice, it rarely is performed. Blood cultures are valuable in individuals with disease caused by group B streptococcus, *S. pneumoniae*, and *H. influenzae* type b.[74]

Group B streptococcal cellulitis occurs in neonates and generally is seen as part of invasive, late-onset disease. Unilateral involvement of the face or submandibular sites occurs most commonly, but inguinal, scrotal, and prepatellar involvement has been described.[10,68] When cellulitis occurs in an infant younger than 3 months old, group B streptococcal bacteremia should be suspected, even in the absence of other signs of systemic infection.

Pneumococcal soft tissue infections are common findings.[109] Patients with connective tissue disorders, such as systemic lupus erythematosus, seem especially prone, although these infections can occur in healthy infants and children. Sites of involvement include the head, neck, leg, and torso.

H. influenzae type b cellulitis often involves the face of infants (Fig. 60A-4). A violaceous hue of the cellulitic area, which some researchers thought to be pathognomonic, might be observed. This process nearly always was the result of hematogenous seeding by *H. influenzae* type b, and meningitis occurred in 15 to 20 percent of such patients.[67,128,139] As has been the case with other forms of *H. influenzae* type b disease, almost complete eradication has been achieved in the last decade with the use of conjugate vaccine.

FIGURE 60A-4 ■ Buccal involvement in an infant with invasive *Haemophilus influenzae* type b disease.

Treatment of simple cellulitis in patients with a clear-cut area of preceding trauma should include an agent that is active against *S. aureus* and group A β-hemolytic streptococcus, and in most locales, clindamycin remains a good choice for therapy, although resistance for *S. aureus* (10% to 15%) and group A β-hemolytic streptococcus (2% to 3%) is noted. The aforementioned caveats for treating staphylococcal skin infections should be followed. In infants with buccal or periorbital involvement or in infants with soft tissue involvement but without a clear-cut focus of infection, a third-generation cephalosporin, such as cefotaxime or ceftriaxone, should be included with clindamycin. Vancomycin always should be included in cases of a patient who is toxic and when metastatic suppurative disease is suspected.

NECROTIZING FASCIITIS

Necrotizing fasciitis is a rapidly progressive bacterial infection of the soft tissues associated with a fulminant course and a high mortality rate. This infection spreads rapidly in the plane between the subcutaneous tissue and superficial muscle fascia and causes widespread necrosis. Prompt and aggressive medical and surgical management is necessary to ensure a good outcome.

In children, necrotizing fasciitis usually is caused by group A β-hemolytic streptococcus; traumatic lesions involving the skin, including varicella, burns, or eczema, may predispose to this aggressive process.* An association has been noted among varicella, ibuprofen use, and invasive group A β-hemolytic streptococcus infection, although no data convincingly link this triad to necrotizing infection.[53,90,141] Patients with congenital or acquired immunodeficiencies are at greater risk for the development of necrotizing fasciitis, and in neonates, omphalitis and circumcision are predisposing conditions.

Clinical Manifestations

The child generally has a high fever and is fussy. In infants, the irritability may be profound and may not appear to be localized to an involved site, unless the clinician is meticulous in conducting the examination. An extremity most commonly is involved, and older infants and children often refuse to bear weight or move the affected extremity. Swelling of soft tissue usually is noted, but the erythema may be subtle. The hallmark tip-off on examination is the finding of intense pain on manipulation of the involved site that is out of proportion to the cutaneous signs. Skin changes that occur during the subsequent 24 to 48 hours include blistering with bleb formation, and a dusky appearance of the involved site is noted as vessels are thrombosed and cutaneous ischemia develops. Skin necrosis is a late sign and indicates a poor prognosis (Fig. 60A-5).[77,134]

*References 18, 46, 54, 58, 68, 107, 118, 119, 142.

FIGURE 60A-5 ■ Necrotizing fasciitis in a toddler with varicella.

Recognition of the manifestations of toxic shock syndrome (see Chapter 64) is crucial because mortality rates of 60 percent have been reported in patients with associated fasciitis. Multisystem complaints, including vomiting, diarrhea, and severe myalgia, are present when group A β-hemolytic streptococcus fasciitis is associated with streptococcal toxic shock syndrome. Tachycardia out of proportion to fever and altered mental status may be early signs of toxic shock syndrome. Renal and hepatic dysfunctions occur typically, and signs and symptoms of acute respiratory distress syndrome often are identified.

Diagnosis

The diagnosis cannot be based on the appearance of the involved site because none of the early findings of necrotizing fasciitis are pathognomonic. Plain radiographs usually are normal and of no value in establishing the diagnosis. Magnetic resonance imaging (MRI) is the preferred technique to detect soft tissue involvement. MRI permits visualization of the soft tissue edema infiltrating the fascial planes.[20,112,143] Although MRI may be helpful, it should not delay performing surgical intervention. Waiting for a radiographic procedure to be performed to confirm the diagnosis may serve only to delay implementing definitive surgical therapy and to increase the risk for development of systemic complications, contributing further to the increased morbidity and mortality rates. In the typical clinical scenario in which the index of suspicion for necrotizing fasciitis is high, surgical exploration is appropriate, even in the presence of "normal" MRI findings.

Laboratory manifestations of streptococcal toxic shock syndrome should be sought in any pediatric patient with fasciitis. Typically, the white blood cell count is normal; however, most patients have a significant increase in band forms (>50%) noted on the peripheral blood smear. Thrombocytopenia and evidence of coagulopathy are found commonly, and marked hypoalbuminemia with hypocalcemia is a typical finding. Laboratory findings associated with renal failure, myocardial dysfunction, and acute respiratory distress syndrome may develop during the first 48 to 72 hours.

A microbiologic diagnosis can be made by isolating bacteria from blood, tissue, or wound culture. In some cases, a polymicrobial etiology has been noted, particularly in patients with so-called Fournier gangrene or necrotizing fasciitis of the perineum.[48,73] In these cases, *S. aureus*, group A β-hemolytic streptococcus, and one or more anaerobes, including *Peptostreptococcus*, *Prevotella*, *Bacteroides fragilis*, and *Porphyromonas*, have been implicated in infection.[19] Fasciitis caused by *P. aeruginosa* or *Clostridium septicum* has been seen in neutropenic patients. In the last decade, group A β-hemolytic streptococcus has been reported widely as a single pathogen and is the etiologic agent in most cases of pediatric fasciitis. As in other cases of invasive disease caused by group A β-hemolytic streptococcus, virulence is related to certain structural characteristics of the organism and to its ability to produce biologically active substances, some of which facilitate invasion and spread of the pathogen.

Treatment

Surgical débridement of necrotic tissue is the key to managing necrotizing fasciitis, and increased mortality rates have been observed when débridement is delayed more than 24 hours.[104] Mandatory return to the operating room for examination and repeat débridement should occur during the following 24 to 48 hours. Careful management of fluids, attention to pain control, anticipation and management of multisystem organ failure, and administration of appropriate parenteral antimicrobial therapy should be initiated promptly. The use of intravenous immunoglobulin may be considered in cases of toxic shock syndrome–associated fasciitis.[24]

Appropriate therapy includes intravenous penicillin 150,000 U/kg/day divided into four to six doses, clindamycin 40 mg/kg/day divided into four doses, and vancomycin 40 mg/kg/day divided into three to four doses. The use of additional coverage with agents active against *P. aeruginosa* and gram-negative enteric organisms should be considered in neutropenic patients.

Response to therapy is assessed by careful serial examination. Control of pain is crucial in such patients, while keeping in mind that persistent, severe pain suggests ongoing tissue necrosis and may signal the need for further surgical intervention. Careful attention to nutritional support should be maintained throughout the child's hospital stay. Physical therapy is necessary for most patients, especially patients who require

amputation, skin grafting, or extensive reconstructive surgery, and providing for the psychosocial needs of the child and the family is imperative.

CONTAMINATED WOUNDS

Although staphylococci and streptococci are the most likely causes of infection after traumatic skin lesions, the list of causes may be extensive, depending on the nature of the injury. Specific pathogens should be considered when infections develop after human or animal bites, soil or water contamination, or various types of injury. Management of such infections depends on recognizing infection patterns and obtaining cultures for careful identification of the specific organism or organisms involved (Table 60A-2).

Human Bites

Two types of human bites are described: occlusional and clenched fist (see also Chapter 248). Occlusional bites are related most commonly to child abuse, although in a pediatric patient, a biting toddler may be the culprit. Accidental bites may occur during sporting activities and generally involve the face of a teammate. Clenched-fist injuries are associated with the most prevalent and severe infections that occur after human bites. Rapidly progressive infection may follow despite the patient receiving early medical attention.[11] When clenched-fist injuries are associated with bite wounds, laceration and puncture wounds commonly occur along the dorsal aspect of the third metacarpophalangeal joint, and bone, joint capsule, or tendon structures may be involved.

TABLE 60A-2 **Infections Associated with Animal Bites**

Nature of Injury	Pathogens Involved
Human bites	Staphylococci
	Anaerobic and aerobic streptococci
	Eikenella corrodens
Animal bites	
Dog and cat	*Pasteurella* spp
	Staphylococcus aureus
	Streptococci
	Anaerobes
	Capnocytophaga canimorsus, Capnocytophaga cynodegmi
	Moraxella spp
	Corynebacterium spp
	Neisseria spp
Reptile	Enteric gram-negatives
	Anaerobes
Horse and sheep	*Actinobacillus* spp, *Pasteurella* spp
Pig	*Flavobacterium* spp, *Actinobacillus* spp, *Pasteurella aerogenes*
Rat	*Streptobacillus moniliformis, S. aureus*

Polymicrobial infection is the usual finding, and in such cases, broad-spectrum empirical antimicrobial coverage should be initiated promptly, after adequate drainage has been performed.[117] In a multicenter study of infected human bites, the median number of isolates per wound was four, and aerobes and anaerobes were identified. The common pathogens were *Streptococcus anginosus*, *S. aureus*, *Eikenella corrodens*, *Fusobacterium nucleatum*, and *Prevotella melaninogenica*. *Candida* spp. were noted less commonly.[131] Many strains of *Prevotella* and *S. aureus* are β-lactamase producers, and *E. corrodens* is intrinsically resistant to clindamycin and cephalosporins. Ampicillin with clavulanate given orally (simple infections) or ampicillin-sulbactam given intravenously for more complicated infections may be used as a single agent. Unusual pathogens rarely occur. A report of a human bite infection caused by *Mycobacterium ulcerans* is noted; this pathogen is emerging rapidly in West African countries.[35] Antimicrobial prophylaxis should be considered for patients with human bites to the hands, feet, and skin overlying joints and for patients with bites that penetrate deeper than the epidermal layer.[115]

Animal Bites

Animal bite wounds occur commonly, with more than 4 million reported annually in the United States (see also Chapter 248). Children account for more than half of patients who go to emergency departments for care of bite wounds.[2] Although one survey revealed that rodents and lagomorphs are the biting animals most commonly reported, wounds related to these bites seldom are associated with infection. By contrast, cats and dogs together account for approximately 40 percent of bites and their bites are associated more frequently with morbidity. The etiology of animal bite infections often is related to the species of animal involved (see Table 60A-2).[40,43,75,93]

Approximately 1000 emergency department visits related to dog bites occur each day, at a cost of more than $100 million/yr.[127] The incidence of infection related to dog bites has been estimated at 3 to 17 percent.[9,34] Cat bites are most likely to become infected, probably because of the puncture-like nature of the injury. One study suggests that half of cat bites result in infection, prompting recommendations for prophylaxis of such bites, especially if they involve the face or hands. In the presence of infection, exploration plus débridement of devitalized tissue is necessary, and purulent collections should be drained.

Although *Pasteurella multocida* is implicated most frequently, numerous other pathogens, including *S. aureus*, *Capnocytophaga canimorsus*, and other aerobic and anaerobic bacteria, are associated with dog and cat bites. Depending on the depth of the wound's penetration, underlying structures such as bones, joints, and tendons may be involved in such infections.[59] The wound itself may not appear significant, particularly in the case of puncture wounds, but several clinical features should influence treatment decisions. The presence of tissue edema and point tenderness on palpation over the site should signal that deeper structures may be involved. Soft tissue imaging may be necessary, and appropriate

drainage or débridement of involved sites should be pursued.

As with human bites, oral amoxicillin-clavulanate may be used for prophylaxis or treatment of simple infections. Indications for prophylaxis of bite wounds include bites associated with a crush or puncture injury and bites involving the face, hands, feet, and genitalia. Wounds in immunocompromised, especially asplenic, individuals should be considered for prophylaxis. Intravenous ampicillin-sulbactam or ticarcillin-clavulanate can be used for more serious infections. For individuals who have a history of anaphylaxis with penicillin or cephalosporins, a combination of clindamycin plus trimethoprim-sulfamethoxazole or ciprofloxacin can be used.[112,114] Antimicrobial therapy may be modified further depending on the biting animal and suspected pathogen (see Table 60A-2).[13]

Appropriate prophylaxis against tetanus should be considered for all bites. Hepatitis B can be transmitted by human bites, and appropriate management should be ensured for susceptible patients. Rabies vaccine should be administered after bat, skunk, or raccoon bites; public health information should be accessed to decide whether rabies vaccine is indicated for other animal bites.

TABLE 60A-3 **Infections Associated with Soil-Contaminated or Water-Contaminated Wounds**

Soil-Contaminated Wounds
Staphylococcus aureus
Group A β-hemolytic streptococci
Many gram-negative enterics
Enterobacter cancerogenus
Anaerobes
Nocardia asteroides, Nocardia otitidiscaviarum
Mycobacterium fortuitum, Mycobacterium abscessus
Actinomyces
Aspergillus spp
Enterococcus spp
Water-Contaminated Wounds
Aeromonas hydrophila
Pseudomonas spp
Many gram-negative enteric organisms
Edwardsiella tarda (catfish injury)
Mycobacterium marinum

Soil-Contaminated and Water-Contaminated Wounds

Four factors that must be considered in the acute care of contaminated wounds include the (1) mechanism of injury, (2) the length of time that transpires from injury to treatment, (3) the type of pathogens that occur in the environment, and (4) the presence of underlying disease in the host.[42] When a traumatic wound becomes infected, a polymicrobial etiology is typical, and common pathogens such as *S. aureus*, gram-negative enteric organisms, and anaerobes characteristically are involved.[1] Unusual and rare organisms, such as nontuberculous mycobacteria; *Nocardia; Actinomyces;* fungi, including *Aspergillus* spp.; and unusual gram-negative organisms, occasionally may be encountered (Table 60A-3).[84,98,99,101,137] *A. hydrophila* has been implicated in infections associated with injuries contaminated by fresh water and may produce rapidly progressive wound infection with fascia, tendon, muscle, bone, or joint involvement.[120]

Managing wounds contaminated by soil or water is difficult, especially if the mechanism of injury is a catastrophic event with complex bone and soft tissue injuries. In the acute setting of such an event, complete exploration and thorough débridement with copious irrigation are performed primarily, and signs of infection generally are not present. Days later, the clinician often is faced with the dilemma of a patient who is receiving antimicrobial prophylaxis with broad-spectrum agents and in whom new signs or symptoms develop acutely. Separating infectious from noninfectious complications often is difficult; however, the onset of fever in such a patient, especially in the setting of an open fracture or dural tear, should prompt further evaluation. Careful serial examination of the site of injury is necessary, and more extensive evaluation generally is indicated. Such assessment may include radiographic imaging and specific evaluation of body fluids with appropriate cultures. Because open fractures are associated with an increased risk for development of infection, the utility of antibiotic-impregnated implants, which are biodegradable and osteoconductive, may prove beneficial in such cases.[132,138]

Infections associated with foreign bodies such as wood generally cannot be cured until the foreign body is identified and removed.[140] Puncture wounds should be explored carefully, and further débridement of necrotic tissue or drainage of involved sites such as joints may be necessary.[8]

Treatment of simple wound infections associated with soil or water contamination should include an agent such as ciprofloxacin, although deeper tissue infection may develop after a seemingly innocuous injury, and tissue débridement may be necessary. Determining the appropriate therapy for a patient with infection involving extensive soft tissue injury and open fractures is problematic. Administration of an empirical regimen with an agent such as piperacillin-tazobactam, imipenem, or a fluoroquinolone plus vancomycin may be reasonable after evaluation and appropriate culturing have been done.

60B VIRAL AND FUNGAL SKIN INFECTIONS

Meena R. Julapalli • Moise L. Levy

VIRAL INFECTIONS

Cutaneous manifestations of viral infections are common. Exanthems often accompany acute viral infections. This chapter focuses on the common viral illnesses that manifest with cutaneous manifestations. More detailed information on each of these illnesses can be found in the chapters devoted to specific viral agents.

Viruses can invade the skin indirectly as a result of viremia or directly, as with warts or molluscum. Other mechanisms of producing exanthems include interactions between the infecting agent and humoral or cell-mediated factors or a systemic immune response in the absence of viral antigen in the skin.[63]

The type of exanthem encountered depends on the virus, the pathophysiologic mechanisms involved, the location of the eruption, and local and systemic immune factors. A single virus may manifest with a variety of cutaneous reactions within the same host. Clinicians caring for a patient with an exanthem usually are faced with a challenge to determine its cause. Most viral exanthems are benign and self-limited, but understanding the exact cause can be important when evaluating immunocompromised patients or in the setting of a fetus. Similarly, distinguishing a viral exanthem from skin eruptions caused by other infectious agents or drugs is important.

Generally, children presenting with fever and a rash cannot be diagnosed accurately by the presentation of the eruption.[29] The distribution and character of exanthems, such as the often characteristic reticulated erythema after "slapped cheek" exanthem typical of parvovirus B19 infections, are helpful; however, the virus can manifest with several other cutaneous findings.[10,45,48] Typical hand, foot, and mouth syndrome is caused by coxsackievirus, although it has been related more recently to enterovirus 71.[12] The concurrent administration of antibiotics in the setting of Epstein-Barr virus infection is important to know, as is the possible relationship between human herpesvirus infection and certain drugs resulting in drug rash with eosinophilia and systemic symptoms.[13]

Laboratory studies, in addition to specific viral cultures, polymerase chain reaction, and serologies, may be helpful in distinguishing between viral and bacterial diseases or drug eruptions. Coagulation studies may help clarify whether a purpuric eruption is caused by a primary coagulopathy or a viral process. Other laboratory tests, such as streptococcal screens or throat cultures or both, serum antibody titers, viral cultures, and antigen detection methods, are required for evaluating exanthems, depending on the state of the patient being evaluated.
